In case 1 the patient showed pronounced euphoria, and early in treatment she had far less pain in her leg; after the intravenous therapy was discontinued she could walk about the ward in contrast to her bedridden state on admission. The other 2 patients showed no such objective improvement. Case 2 continued a rapid and miserable decline, and the patient died deeply jaundiced 10 days after the intravenous A.C.T.H. was discontinued.

These 3 cases were far advanced and no general conclusions can be drawn with certainty from this very limited experience. We feel, however, that further clinical trial on similar lines is not at present justifiable.

Bristol. W. G. MACGREGOR.
Oxford. CHARLES L. LEWIS.

CHLORIDE DEPLETION IN INFLUENZA

SIR,—In the current influenza epidemic, one of the most constant findings in our patients has been prolonged and severe sweating, irrespective of the height of the initial pyrexia. Some patients described rivulets of sweat trickling down the skin.

The resultant loss of fluid and chlorides was, in one case, probably the cause of cramp of the abdominal muscles, simulating an "acute abdomen."

I was called to a man, aged 45, late one evening. He had agonising abdominal pain, causing him to writhe about his bed. He had been unwell for two days, but had tried to carry on with his work. His main complaints had been excessive sweating and general malaise. His daughter was recovering from influenza.

He was pale with sunken eyes, and he was in a cold sweat. His temperature and pulse-rate were subnormal. The blood-pressure was 110/75 mm. Hg. His tongue was dry and furred. The abdominal muscles were rigid, and there was slight tenderness in the epigastrium. The heart and lungs were normal. While I was with him, he had an attack of abdominal pain which doubled him up, lasting about three or four minutes and ending in vomiting.

Approximately 4 g. of salt in orange juice was given slowly by mouth and retained. A specimen of urine showed specific gravity 1028 and chlorides 1·6 g. per litre, indicating salt depletion.

He subsequently had no further attacks of pain, and made an uneventful recovery.

Although one cannot categorically assign the cause of the pain to the salt depletion alone, it is likely, on probabilities, that it was the rapidity of the fall in the plasma-chloride level coupled with the evident dehydration that precipitated the crisis. I consider the case worth recording in view of the uncommon complication in a common ailment.

It is interesting to speculate on the clinical similarity between postinfluenzal depression and moderate salt depletion. One recalls the loss of appetite, mental apathy, and muscular weakness of servicemen suffering from heat exhaustion in the tropics, and the response to the administration of salt.

The poor appetite which occurs regularly after a bad attack of influenza is what might be termed epicurean. The "choosiness" is a desire for savouries rather than sweets, the inference being that the salt content of the former is temporarily more in demand by the body fluids.

The routine administration of Dover's powder with aspirin to get a "good sweat" is, on this hypothesis, sound treatment only if the chlorides lost in this way are subsequently replaced by the oral administration of salt.

Shap, Westmorland. L. E. WEAR.

SEDATIVES IN THE PREPARALYTIC STAGE OF POLIOMYELITIS

SIR,—In a large epidemic of poliomyelitis in the Brunswick area (500 cases, of which 115 were admitted to our hospital) we administered sedatives to all children in the preparalytic stage in order to intensify the physical rest which is so important then. An initial dose of 0·4–1 ml. of 'Somnifaine' (Roche), according to age, was given intramuscularly, and oral administration was continued for some days to ensure continuous sleep, though the children could be roused. Of 39 children thus treated 4 developed paralysis, while of 26 untreated children 5 developed paralysis—i.e., about 1 in 10 of the treated, but 1 in 5 of the untreated. In a further 23 cases with paralysis on admission which were treated in the same way the paralysis did not develop to such an extent as in an equal control group.

The suggestion is that sedative therapy (*Schlaftherapie*) will probably prove successful, though the present figures are too small for a decision. The following clinical and experimental facts indicate the rationale of sedative treatment in poliomyelitis.

1. Russell[1] and Horstmann, who compared two large groups, showed that the risk of paralysis is some 140% greater if the patient does not rest completely after the onset of preparalytic symptoms.

2. According to Bodian[2] a "hovering state" exists (Sabin calls it an "armed truce") in the relationship between the virus and the cell, and in our opinion it is still possible during this time to stop the chromatolytic destruction of the anterior horn cell.

3. Under normal conditions every muscular action uses up a certain amount of cytoplasm in the anterior horn cell (proteins and ribosenucleotides). Growing like a parasite the virus also uses up the same substances in the cells. Thus it is evident that an anterior horn cell invaded by a virus and also functioning through muscular action is likely to be destroyed quickly and irreparably.

4. Trauma, vaccinations, painful peripheral contractions and selective action of groups of muscles modify the physiological condition of the spinal cord and locally increase the vulnerability of the nerve cells connected with the "traumatised" area.[1 3-5]

5. Each anterior horn cell is connected with a variable number of muscle fibres—a few only in the case of small muscles (5 to 6 in the external rectus), but many in the case of large muscles (120–160 in the gluteus), and therefore the intracellular metabolism is higher in those cells which supply

greater good of the health of the people can and should be exported. But the social scientist can advise on the rate and the form in which these ideas can be most effectively introduced.

Place of the Social Scientist in Medical Training

"Medicine is an aspect of social policy," said Dr. J. H. F. **Brotherston** (lecturer in public health, London School of Hygiene and Tropical Medicine); and he too regretted that science has almost captured medical training. He thought the time has come to strike a fresh balance, but he was anxious not to suggest that the doctor's training is poorly organised or planned. Indeed he believed the quality of medical education and the professional stamina of doctors to be good. But he suggested that the organisation of medical practice has fallen behind the development of the medical sciences. The black-bag era of medicine ended long ago and now the care of the patient is isolated into compartments with a poor system of inter-communication. He was sure that a long overdue reform is to bring those looking after the patient closer together. But his most important criticism of the general practitioner's training was that it does not prepare him for conditions of practice outside hospital.

Clinical science is so complex that the bulk of medical training must remain in the laboratory and at the hospital bedside, but Dr. Brotherston sees the solution of this dilemma in the fact that the hospital is a community institution

> ". . . in no way separated from the outside world or from the rest of the system of medical care. If the sense of community interest permeates the hospital teaching of the student, and if the place of the hospital can be kept in perspective for him while in hospital, the importance of the function of providing medical care outside the hospital will be much more apparent to him that it sometimes is at present."

One way of achieving this, Dr. Brotherston suggested, is to lay more importance on the teaching of social medicine. Such teaching techniques as the case conference, he thinks, are useful in diverting the student's attention from the hospital to real life, but they are not the whole answer. At present, though the student is trained to think scientifically about his clinical problems, no effort is made to teach him to look with scientific detachment at the social situation in which he must practise. Communication between doctor and patient is another skill which in Dr. Brotherston's opinion is neglected in the curriculum. More emphasis should be put on the empirical art of dealing with the patient as a person as opposed to the science of studying his disease processes.

The student should also be taught the history of medicine in such a way as to make him appreciate the changing rôle of the doctor. A knowledge of the terms of service of his profession in the past would help him to look objectively at the developments of the future. Indeed, Dr. Brotherston found that the medical profession is haunted by lingering loyalties to arrangements developed to deal with situations that no longer exist. For instance we have barely managed to re-equip and reorganise our hospitals as diagnostic and treatment centres, though it is more than two generations since they ceased to be mere refuges for the pauper infirm. In this process of centralising expensive equipment and skill the hospital has acquired a life of its own, and now we fail to recognise that it is after all only a convenient means of centralising certain resources of the community. As a result, we have failed to expedite the possibilities which improved housing offers of delegating back to the home some of the residential functions of the hospital. But medical sociology can only be diffused through the doctor's training with the guidance of the sociologists, and Dr. Brotherston asked their help in collecting a body of knowledge of the social sciences and in translating it into terms appropriate for the medical student.

Hospital Organisation under N.H.S.

Mr. T. E. **Chester**, dr. jur. (acting director, Acton Society Trust) thought this part of the service improved both in quantity and quality, especially in neglected provincial areas. Some of the problems of today, such as the lack of accommodation for the mentally sick, are legacies from the past, but others have arisen during the change-over to the N.H.S. Apart from transient growing pains they fall into two groups. The first group are due to environmental factors which though not inherent in the organisation have shaped its development. Thus the under-budgeting of the first year led to a hasty tightening of central control, and continuous economic difficulties to the imposition of an arbitrary ceiling. Again shortage of staff is general in industry and is due to full employment rather than to the N.H.S. Into the second group Dr. Chester gathered the real problems inherent in the service itself. Some centres on institutional framework—such as the best size for the different administrative units, the hospital, the hospital management committee, and the region. Some problems, centred on the relation between the different levels of the organisations, raise such points as centralisation versus decentralisation, specialisation versus coördination, and flexibility versus uniformity. Other important problems centre on staffing—especially on the quality of the paid administrator and of the 10,000 voluntary committee members on whose joint ability the success of the N.H.S. ultimately depends.

Social Needs and Costs

Mr. R. M. **Titmuss** (professor of social administration, University of London) recalled that the economic attack on the social services on grounds of lavishness and undue rapidity has grown during the last few years, and successive governments have limited expenditure. Critics seem generally agreed that the main cuts should fall on the N.H.S., and, within the N.H.S., in the hospital sector. Beneath the debate on the cost of the social services seems to be the assumption that they are concessions extracted from one class for the benefit of another, but this point of view takes little account of the social changes of the past century.

> "We find ourselves still heavily weighed down by thoughts of benefactions and beneficiaries: still dependent on outworn notions of what constitutes a social service 'need'; still regarding these services as ends rather than means; still attaching to them a supernumerary and separate rôle in the social system . . . we have not yet developed an adequate theoretical framework within which the dynamic rôle of the social services can find a balanced appraisal as an integral part of the total performance of the social system."

It is not easy to think clearly about social services, Professor Titmuss pointed out, when we are not even sure what a social service is. It seems almost accidental whether a particular need when met is regarded as a social service. Juvenile crime, for instance, is met by a social service, but not adult crime; family allowances are a social service but not child allowances as remission of tax. In the midst of this confusion attempts to compare the costs of the social services today with those before the late war are unrealistic.

In a modern community the needs of the poorer sections of the population are met by the "redistributive" social services, while similar provision in the sense of transfer payments in favour of dependent groups among the better-off sections are not always so classified, though they may cost the public dear. There is thus confusion of thought and practice over the social costs arising from the needs of childhood, old age, and ill health. The social services also meet the concealed "disservices" of our modern world, caused by such things as premature retirement from work, reduced earning-power, and deterioration in skill. Despite these growing if hidden burdens, the total of hospital beds, for instance, in relation to the population was smaller than accommodation in doctors' premises under the National Health Service, how many had been inspected by executive councils, and how many had been declared unsuitable —Miss HORNSBY SMITH replied The relevant regulation is paragraph 7 (4) and (5) of part I of the first schedule to Statutory Instruments 1948, no 506 The Minister has no details of inspections by executive councils, he is, however, hoping shortly to discuss the best way of securing an improvement, where necessary, in the condition and equipment of general practitioners' surgeries and waiting rooms with representatives of the medical profession

Mr ARTHUR BLENKINSOP Will the Minister agree that the attention of the executive councils might well be drawn *to this matter, especially in view of the considerable sums of* back pay recently awarded to the medical profession, and that this may be one of the most desirable ways of utilising at least some of that money ? Miss HORNSBY SMITH I think that we should await the outcome of the discussions which are pending

Capital Allocations to Hospitals

Mr KENNETH ROBINSON asked the Minister what special capital allocation he was making for the coming financial year to meet the needs of the mental hospitals —Mr MACLEOD replied It is for regional hospital boards to decide what particular projects shall be included in their capital programmes, but I have again asked them to devote at least 20% of their allocations to mental health projects In addition, two major mental health schemes are being financed from a special central reserve Of course this is probably the most serious problem facing the National Health Service, and it is precisely for that reason that I insisted upon the minimum figure I have given The position would have been a great deal easier if, in the first year or two of the health service, a larger proportion of resources had been devoted to the mental field

---

Public Health

Smallpox

BY March 27 the number of confirmed cases of smallpox in the outbreak in Lancashire and the West Riding had risen to 16 including 11 at Todmorden, 2 at Bacup, and 2 at Bury There have been no more deaths since the second one on March 20 In Todmorden 2 general practitioners and a number of their patients have been placed in quarantine Dr J Lyons, medical officer of health for Todmorden, said that it was too early to say that they had beaten the outbreak, but they had localised it[1]

Replying to a question in the House of Commons, Mr Iain Macleod, the Minister of Health, said that the outbreak started among workers at a spinning mill at Todmorden who handle imported raw cotton It seemed possible that the cotton was the source of infection There was no evidence from previous experience that the disease could be spread by cotton except in its raw state, or as cotton waste None of the recent cases had occurred outside the range of known contacts with the original cases The Minister added that he had asked the Medical Research Council to investigate the highly technical and difficult question of the transmission of smallpox by raw cotton Replying to supplementary questions, he said that there had been some delay in diagnosing the first case, but this was not surprising, because, happily, doctors in this country saw virtually *no smallpox* There was not the slightest danger of infection being spread by cotton yarn or clothing, or by any finished materials made from that particular cotton All possible steps had been taken to isolate the suspected bales of raw cotton

Influenza

In the week ended March 14 there were 139 deaths from influenza in the 160 great towns of England and Wales In the three preceding weeks deaths numbered 321, 314 and 193 So far this year there have been 2710 deaths from influenza in the great towns, compared with 393 in 1952 and 7247 in 1951 The number of claims for sickness benefit received by the Ministry of National Insurance (including Scotland) is still in excess of last year's figure, but the weekly total has been falling steadily since the week ended Feb 17

Diphtheria Prophylaxis

In a circular to local authorities and medical officers of health, the Ministry of Health says that an intensive effort must be made to achieve the level of immunisation necessary to secure the full benefit of the campaign against diphtheria The object of the campaign remains the same to secure the immunisation of not less than 75% of babies before their first birthday During the first half of 1952, however, only 31% of the estimated number of children reaching the age of one year were immunised, and though this is 3% higher than the figure calculated for 1951, it is "disturbingly low" In an illustrated brochure accompanying the circular, Sir John Charles, chief medical officer of the Ministry emphasises the importance of these figures, and calls for "a sustained effort of persuasion directed to each generation of new mothers" The brochure includes a newly designed health visitor's card and general leaflet, which will supplement the campaign conducted by press advertisements, posters, and cinema slides

Scotland in 1952

In a preliminary return for 1952 the Registrar General for Scotland[1] reports that the provisional figures for tuberculosis show a further decline in the death rates from both pulmonary and non-pulmonary disease The death-rate from all forms of tuberculosis was 0 32 per 1000 population, compared with 0 37 in 1951 and 0 66 in 1948 The birth-rate was 17 7 per 1000 population—the same figure as in 1951 The stillbirth rate —26 per 1000 total births—was 1 less than in the preceding year The infant-mortality rate of 35 per 1000 live births was 2 less than in 1951 and 9 less than the average for the previous five years This was the lowest infant-mortality rate yet recorded in Scotland.

The Delicate Child

Writing in the report of the county medical officer for the West Riding of Yorkshire, Dr C C Harvey pædiatrician to the West Riding County Council dismisses the "delicate child" as an "iatrogenic artefact"

"By the hesitancy and caution of our pronouncements, by our emphasising the wrong aspect of a situation, or by the failure of inadequate treatment, we easily confirm parents' worst fears Behind our backs they are also subjected to morbid grandparental gossip and the cryptic hints of the lady in the bus queue At our best we wage a defensive struggle against the scorn of dogmatic parents, loth to lose the glamour of abnormality and disease which they have cast over their children Symptoms grow up round a supposed defect discovered casually, such as the 'breathlessness on effort since infancy, with lips going blue on exercise' pinned upon a normal child with innocent heart murmur and full effort tolerance There was also the twelve year old boy with postural (not rheumatic) pains due to crouching permanently over a television set procured to keep his (innocent) heart murmur away from football fields My records of innocent heart murmurs still out number the rheumatic hearts If we consider the wastage of school time between 7 and 11, which is educationally irremediable, we need to review the fallacy that 'health is more important than success' Scores of children are kept off school months at a stretch, instead of half days, with 'bronchitis' I assume it is because we cannot trust ourselves to ascertain that it is non tuberculous In nearly all such cases, lengthy absence contributes nothing to health while precluding scholastic success Such children adequately handled, could usually enjoy both health and success We need to establish that normal people are entitled to certain normal pains, among which stomach ache can be a respectable diagnosis, once organic causes are fairly eliminated One Grammar School girl lost five weeks with a sick dizzy sinking feeling on rising which amounted to healthy hunger contractions "

HUMAN FACTORS IN INDUSTRY

THE Department of Scientific and Industrial Research and the Medical Research Council have jointly set up two committees to work on human problems in industry One will study individual efficiency , the chairman of this committee is Sir Frederic Bartlett, F R S , its medical members are Prof Esther Killick and Prof W E Le Gros Clark, F R S , and the joint secretaries are Dr Brandon Lush and Mr Winston Rodgers The second committee, which will deal with human relations, has Mr A B Waring as chairman and Prof T Ferguson, Prof A J Lewis, and Dr A T M Wilson as medical members , the joint secretaries are Mr J R Gass and Dr Lush

BUYING FOREIGN BOOKS

LAST month a peripatetic correspondent described the formalities that had to be completed before he could pay for a book published in a foreign country[1] UNESCO, we learn, has an international scheme by which the purchaser obtains with his own currency dollar coupons which are cashed with UNESCO by publishers or booksellers in any of the countries participating in the scheme These coupons are intended to enable institutions and individuals to obtain publications in the fields of education, science, and culture , and they may be used not only for books but also for subscriptions to periodicals for copies and for membership subscriptions to learned societies provided that the subscription is mainly a means of obtaining the society's publications In the United Kingdom applications for coupons should be sent to Unesco Book Coupons, c/o Book Tokens Ltd , 14, Buckingham Palace Gardens, London, S W 1

NEW GENETICS JOURNAL

THE *Journal de Génétique Humaine*, the first journal in French on this subject, began publication about six months ago, edited by Prof A Franceschetti, of Geneva, Prof L Van Bogaert, of Antwerp and Prof Maurice Lamy, of Paris It is to be issued four times a year There are English and German summaries An unfortunate system of pagination mars the production of at least the first two numbers each of which has individual pagination, with an indication of the volume pagination on a gummed strip at the head of each strip The publishers are Médecine et Hygiène, 15, Boulevard des Philosophes, Geneva

PROVINCIAL CONVALESCENT HOMES

THE British Hospitals Contributory Schemes Association have published a directory of convalescent homes in the provinces The first issue lists 20 independent homes with details such as almoners may require given in the form used by the King's Fund convalescent homes directory The two directories are thus complementary The association have set a high standard, for although they know of ten times the number of homes they have only published details of those which have been inspected and approved by a responsible almoner A further 28 homes belonging to contributory schemes are listed but without details Copies of the directory may be had (1*s* 6*d* , post free) from the association, Royal London House, Queen Charlotte Street, Bristol, 1

University of Manchester

At recent examinations the following were successful

D P M Part II —K J R Ford, O J Slowik.

International College of Surgeons

This college will hold meetings at the University of Amsterdam on April 8 9 and 10 , at the University of Rome on June 5, 6 and 7 and at the University of Vienna on June 11, 12, and 13 Further information can be had from Dr J F Brailsford, the secretary of the British Chapter of the college, 20, Highfield Road, Edgbaston, Birmingham, 15

Board of Control

Mr H R Green, at present a commissioner of the board, has been appointed a senior commissioner in succession to Mr C I Penton, who is retiring

Manson Medal

This year the council of the Royal Society of Tropical Medicine and Hygiene have awarded the Manson medal to Prof Jerôme Rodhain director of the Institute of Tropical Medicine, Antwerp and the Chalmers medal to Mr David J Lewis entomologist in the Sudan government service

Carlisle 24960

The Carlisle Medical Bureau, which is to open on Wednesday, April 1, will enable a doctor who has to leave his house or surgery unattended to inform the operator on duty of the arrangements for the time he will be away When a patient receives no reply from his doctor's telephone he may then ring Carlisle 24960 for information and help The bureau will be staffed by operators of the fire and ambulance control

CORRIGENDUM *Smoking and Lung Cancer* —In the debate on this subject, reported in our parliamentary columns last week (p 645), Miss Patricia Hornsby Smith said that research into exhaust gases of petrol and diesel engines had not been abandoned as a possible source contributing to cancer of the lung

Dr Albert Sharman as a vice president of the International Fertility Association, representing the United Kingdom is attending the first World Fertility Congress which is to be held in New York from May 26 to 31

Births, Marriages, and Deaths

BIRTHS

MATTHEWS —On March 16, at St Helier Hospital, Carshalton, to Diana, wife of Dr H W Matthews—a daughter (Flora Elizabeth Marguerite)

[1] *Lancet*, March 14, 1953, p 544

pational risk" involved in this perennial professional cul-de-sac. Reading the newspapers, we can see for ourselves that *this job nowadays* carries with it a high degree of legal responsibility. Assuming that some recent judgments have *created* legal precedent, it is a matter for small wonder that applicants for these posts are much too scarce. Absence of prospects plus a risk of *litigation* are hardly inducements. Hence the casualty-officer situation approaches a *crisis*; indeed the crisis has already been reached in some hospitals.

(2) *Registrars*

Now, by official confirmation, the registrar's is another "dead-end" job. A management committee recently protested that the quality of applicants for these posts would inevitably decline because of the denial of advancement to senior-registrar grade save to teaching-hospital registrars. The regional board replied, in effect, that it was not true that only teaching-hospital men would get senior registrarships—it was simply that preference would be given to these men. One may permissibly make the analogy: "coloured applicants are not barred, but it is preferable to be white-skinned." Now, in the midst of our senior-registrar troubles, an advertisement for a senior thoracic registrar specifically invites overseas applicants. One wonders if this is not a novel approach to mitigating the shortage of consultant establishments.

(3) *House-officers*

The chief problem here is surely the disparity between the "attractive" posts where applications are adequate, and the "Cinderella" posts where applications are too few and the hospitals involved are in consequence chronically understaffed. At the one extreme we have the teaching-hospital houseman (commonly with only 12 beds plus "odd-job" duties), and at the other the overworked houseman in the ex-municipal hospital who is too busy to learn, even were modest teaching facilities available. It is surely high time to face the fact that many housemen are getting little but general debility out of their appointments.

We cannot afford to wait for a major crisis *to force* on us a solution to problems which would long have been settled by a modicum of foresight and simple respect and humane consideration for the people involved. One has only to witness the pathetic insecurity of our senior registrars to realise that no-one in power has even bothered to notice that they have homes, wives, and children—let alone that they are *good* specialists with higher degrees, hard-earned for nothing.

London, N.W.3. A. GEE.

OSTEOPATHY

SIR,—I am afraid that Dr. Cyriax misquoted me in his letter (March 21). I know that manipulation is being taught by him, but I still maintain that specific, controlled, and accurate manipulation of vertebral joints is adequately taught only in osteopathic schools. I am fully aware that Dr. Cyriax is making a determined effort to teach manipulation to physiotherapists; but he states in his book *Rheumatism and Soft Tissue Injuries* (p. 392) that in his experience it takes only an hour a week for six of the thirty months of a student's training to impart a good grounding in remedial manual methods. It is my opinion that this is quite *inadequate training.* The properly qualified osteopath spends two years at anatomy, physiology, and basic sciences, then *two further years* in full-time training in the art of manipulation—not just a few hours. Even then he is but at the beginning of acquiring an accurate tissue sense, which is essential to successful manipulation.

When the physiotherapists are prepared to spend two extra years at this work, and when the teaching is on standard osteopathic lines, then I shall be willing to support Dr. Cyriax in his aim at replacing the lay manipulator by the physiotherapist. I consider that until then the physiotherapist-manipulator is as dangerous as the unqualified osteopath.

London, W.1. ALAN STODDARD.

SIR,—One wonders why the word osteopathy is used in connection with the discussion between Dr. Stoddard and Dr. Cyriax since it bears no relationship to the osteopathic theory of health and disease. Dr. Stoddard's point that osteopathic manipulative technique is useful in manipulative surgery is purely incidental to osteopathy, and Dr. Cyriax's physiotherapy students will be taught minor manipulative surgery and not osteopathy.

OSTEOPATH.

CHILD-WELFARE CLINICS

SIR,—I would like to reply to some of the criticisms of the suggestions I made in your issue of Jan. 24.

I agree that the service described by Dr. Lawson (Feb. 7) and provided by Dr. Charlotte Naish (Feb. 7) is an ideal to be striven for, but even such an ideal service would be greatly enhanced by close *integration* between the general practitioner and the health visitor. Far from wishing to "throw it overboard" the aim of my proposals was to assist a greater proportion of G.P.s to give a comprehensive child-health service—a useful start to the process of returning the responsibility for child health to the family doctor.

The present division of services between G.P.s and clinics is generally agreed to be unsatisfactory, but Dr. Gordon (Feb. 21) is prepared to envisage its continuation "until such time as most family doctors are interested in health education and have suitable premises for this work (such as may be provided in health centres)." One possible result of the continuation of this policy would be the discontinuation of centres by local authorities who are seeking to curb their expenditure, as suggested by Dr. Barrow (Jan. 31). Such action is rightly deplored by Dr. Gordon, and it was with a view to bridging the gap until the emergence of health centres that my proposals were made. Admittedly, many child-welfare centres today are in unsatisfactory premises, *but surely the essential need is for the close integration of preventive and curative services.* The buildings will follow.

Dr. Barrow suggests that I have overlooked the time factor. The additional capitation fee for children would be some compensation for the reduction that a G.P. would have to make in his list in order to find the necessary time to *give the children the attention* they deserve. If he is overworked and has not the time to spare, it is unreasonable to expect a doctor to be able to give adequate midwifery and child-health services. There seems to me to be no fundamental reason why general practitioners should not be encouraged to develop their interest in one particular branch of medicine in addition to their general services—they would still be family doctors, responsible for the health of their *patients. In any group of 4–8 practitioners one* could usefully be a G.P. and a pædiatrician and/or obstetrician; but I cannot agree with Dr. Naish that this would not be feasible except in small market towns. I believe that a multiplication of the specialties is undesirable but some degree of specialisation among groups of G.P.s would improve the standards of practice and relieve some of the pressure on *outpatient departments.*

Dr. Gordon says that it would be inappropriate to select 15 of the 70 practitioners in Ilford to look after the children. I agree, of course, but I suggest that the probability would be that he would have some difficulty in getting as many as 15 of the doctors to undertake a comprehensive preventive and curative service. Where group practices exist it would be simply a matter for the group to select one of their members to act as G.P.-pædiatrician for the group; but unless and until group practices become more generalised, these appointments would be sought by G.P.s with special interest in the health of mothers and children and willing to give the necessary time to their proper care.

Oldbury.

H. TABBUSH,
Area Medical Officer.

leading one in the health service—its freedoms or privileges relate both to the individual member of the profession and to the profession as a whole The individual doctor claims, and to a very large degree is granted, personal independence in his care of his patients, acting according to his own informed judgment and being answerable only to his own conscience Apart from a high social status and a power of influence of a degree one sometimes suspects not fully appreciated even by the profession, the privilege of the profession, as distinct from its individual members, is a very large measure of self-government Entry to the profession is controlled by the profession itself and it has power to expel or suspend a doctor from membership At the present time the profession exercises this latter power only in cases of conviction in a criminal court or of infamous professional conduct It could, if thought fit, exercise authority over its members in other respects , but, like most other professions, though perhaps to a somewhat greater extent, it has been reluctant to do so The assumption of greater responsibility for the conduct of its weaker members, when that conduct is detrimental to patients, seems to me to demand serious attention by the profession, not only in the interests of the public but as the profession's surest defence of the freedoms which it prizes

It is not an immutable law of Nature that the profession of medicine, any more than any other profession, should have the privileges it now enjoys These privileges exist by consent of the public, being grounded on the public's respect and confidence, and in its belief, born of experience, that its needs are better met by allowing these freedoms As with academic freedom so with the professional freedoms, they exist because the public is prepared that they should, and they will continue so long as the public—if only tacitly—consents If they are not to be lost or impaired, the profession must give continuing evidence, by the way it fulfils its responsibilities, that, because it has freedom, the public good is better served

Freedom for the Incompetent ?

There is not likely to be much dispute about the general principle , where differences of opinion arise is over its application In his Croonian lectures for 1951 Dr T F Fox, in stating the case for the individual practitioner's freedom, said

> “ we need freedom to serve , we need it because it is indispensable if we are to do our work as it should be done On a short view there are often advantages in interfering with the doctor's freedom, but the public will buy these advantages very dear if it discourages any member of our profession from bringing his own judgment to his patients' problems ”

This is fair and well stated Experience has shown that for the doctor responsibly doing his best the largest possible measure of professional independence is in the best interests of his patients But what of the doctor who is not good ? The man who presumes to a competence he does not, and knows he does not, possess , the man who persistently is negligent , or the man who regularly—and regardless of the fact that he could change the conditions, if he wished—practises under conditions which render good doctoring impossible Without disputing that the numbers in these categories constitute a small proportion of the profession, the public is surely not unreasonable in looking to the profession, as a self-governing body to deal more effectively with these, its weaker members for the better protection of the public It is not a question of the occasional mistake, everyone, whether professional or not, no matter how good he may be, makes mistakes from time to time It is consistent incompetence and persistent neglect that is in question It would be wrong to think that professional action is never taken it is For instance, professional opinion has slowly led to the exclusion of doctors who have not had a long special training in surgery from the performance of all but very minor surgery, except in emergencies But it is true that like other professions, the medical profession has shown great reluctance to accept responsibility for the technical competency and efficiency of its members once they have qualified for membership

The desire to guard against heresy-hunting is sometimes put forward in justification This desire is good , but are we to understand that the profession of medicine is incapable of devising means which would distinguish between those who are incompetent and negligent and those who are honestly unorthodox ? To think so is to doubt unjustifiably its integrity and capacity for self government It is also contended that good doctors might fail to give of their best, might become timid and routine minded rather than constructive, if their standards and conduct of practice were subject to review and judgment even by their *peers*—their professional colleagues This contention is hard to accept That there should be an element of playing for safety—the safety of his patient—in every doctor's decision seems to me desirable And I have not yet been able to convince myself, despite authoritative contentions to the contrary, that medicine differs significantly from other professions in which constructive judgments also have to be made

No matter what sphere he may be in, the competent man is not deterred from doing his best by fear of criticism by his professional colleagues It is the incompetent, or the fellow who has ceased to try, who usually objects, and he is not worthy to have his objections heard Does a judge become timid and fail to do his best because his work is subject to review by higher court and his errors of judgment may be corrected in public by his senior colleagues ? Does the efficient farmer farm less efficiently because he knows that a farmer adjudged by a committee of his farming colleagues to be inefficient may be removed from his farm ? Does the pilot of a jet air-liner or the captain of a ship fail to make the best constructive judgments and to act in the most positive and effective way in face of an emergency which may threaten the lives of those in his care, because his decisions and actions may be subject to expert investigation later ? I cannot resist the feeling that the suggestion which has been made—not only by members of the profession—that medicine is exceptional from the nature of the allegedly constructive decisions which have to be made by medical practitioners, has a flaw in it, and that the medical profession in the essentials of its work is not so unique

Requirements for Entry

The reluctance of the professions to exercise more supervision over their members contrasts interestingly with their great activity in the prescribing and testing of the qualifications of new entrants Let us look at the problem of entrance requirements On training and examinations, there has been and still is a spate of reports, conferences, and “ reforms,” invariably with the result of making the training fuller and longer and the requirements more difficult It is natural and right that a profession should strive to attain the highest reasonable standard of new entrants and a course of pre-entry training that will give them the best preparation for their careers But the over drilling of the innocents should not be a substitute for a proper disciplining of the hardened troops To the public, the quality, ability, and standards of a professional man or woman *five, ten,* twenty, thirty years after qualification are more important than the knowledge and largely unproved skills of the new recruit

Entry requirements to any profession must have a reasonable regard to the actual job which the profession

leading one in the health service—its freedoms or privileges relate both to the individual member of the profession and to the profession as a whole The individual doctor claims, and to a very large degree is granted, personal independence in his care of his patients, acting according to his own informed judgment and being answerable only to his own conscience Apart from a high social status and a power of influence of a degree one sometimes suspects not fully appreciated even by the profession, the privilege of the profession, as distinct from its individual members, is a very large measure of self-government Entry to the profession is controlled by the profession itself and it has power to expel or suspend a doctor from membership At the present time the profession exercises this latter power only in cases of conviction in a criminal court or of infamous professional conduct It could, if thought fit, exercise authority over its members in other respects, but, like most other professions, though perhaps to a somewhat greater extent, it has been reluctant to do so The assumption of greater responsibility for the conduct of its weaker members, when that conduct is detrimental to patients, seems to me to demand serious attention by the profession, not only in the interests of the public but as the profession's surest defence of the freedoms which it prizes

Entry requirements to any profession must have a reasonable regard to the actual job which the profession

overworking I doubt if the authorities or the public yet see clearly the potentialities of medical-social work Hence the confusion, the excessive specialisation that is becoming burdensome, the perfunctory performance by the authorities of fine-sounding declarations of good intentions About a week ago a former junior Minister, in a letter to the *Times*, stated that "if the hospital is to be of the greatest value to the community it must be enabled to use modern techniques fully" By modern techniques he meant new boilers and other heating appliances, sanitary arrangements, laundries, and like items of capital equipment, and he argued for larger expenditure as the road to real economy Of course the things he had in mind are important but better far would be the full development in the health service of the modern technique of medical-social work That is the way to better value for money, to "real economy," and perhaps in time even to a decrease in total expenditure on the service On the one hand are the opportunities to protect ex-patients of hospitals against avoidable loss of benefit received by them from costly hospital treatment Such early studies as have so far been made give a depressing picture of the number of people who a few months after leaving hospital seem no better for the treatment they received On the other hand is the vast work of lessening the need for hospital care by wise guidance of individuals at the right time The early work by almoners and others with the elderly gives foundation for high hopes of what could be achieved

Before these promising fields can be cultivated better, the professions concerned with medical-social work, in cooperation with the authorities need to clear up the developing chaos of types and different qualifications of medical social workers Much has already been spoken on this topic and I need not add to the spate of words but will wait expectantly for the introduction of the all-purposes medical social worker

Opportunity—or Frustration ?

There is a prima facie case that broadly the provision for the medical care of the population is better than it was, and that it could be better still, even within the present framework and under the present "ceiling" of financial resources, if the professions responsible for its operation and their members so determine

Some professional members of the service have been unhappy in adjusting themselves to the new conditions , but on the other hand there are those—people who are first-class at their job—who are fully convinced that they are now able to give better service to their patients than before I cannot myself see cause why any doctor or nurse or member of any of the other associated professions should feel that the National Health Service prevents the rendering of at least as good a standard of medical care as he or she previously gave But there are complaints to this effect There are complaints of frustration needed buildings cannot be obtained , approval for the appointment of additional staff may be refused arbitrarily and without understanding of the need , local initiative is being stifled by excessive, unnecessary, and undesirable centralisation , the hospitals are regimented by the Ministry and they in turn regiment the workers , proper attention and care cannot be given because the number of patients to be dealt with is too large , people have no incentive to do their best and many are becoming time-watchers

Inevitable Limitations

These and like complaints can be classified under two heads those which relate to conditions outside the control of the professions and those which can be dealt with by the professions themselves Let us begin by looking at the first class

Obviously, limiting and irksome conditions exist—for example, insufficient financial resources, the inability to replace bad, inefficient buildings, or to obtain additional staff But there have always been and always will be boundaries to professional activity, boundaries imposed from without by what the public wants or thinks it wants, boundaries which the professions may rightly at times regard as contrary to the public good, but boundaries which nevertheless the professions have to accept until they can persuade the community to change them Such boundaries confined the activities of the medical and its associated professions before the coming of the National Health Service, and the situation is much the same now The total sum made available for the health service and the relatively low priority given to its capital projects are arbitrarily decided it is true, because there is no other way , but they are the guess made by the public's elected representatives—men and women whose political survival depends mainly upon their ability to guess the public's wishes correctly—of how much of the nation s capital and recurrent resources the public is prepared to have devoted to hospitals and the health service generally There are many competing claims on these resources It may be regrettable that the amount spent on the health service is little over one third of the amount spent on tobacco and drink, and is over £100 million less than the estimated amount spent on gambling , but, until the clients change their opinions and habits, the professions have to accept these limitations imposed upon the scope of their professional work *Clearly they have the right to make their views* heard and to use their intimate and special knowledge and all their professional influence in attempts to persuade the public to remove hampering obstacles *But it is* equally clear that in the meantime, if they are to be worthy of professional status and privileges, they must do the best they can within the existing boundaries and with the resources available It is equally clear that they must resist the temptation to make these limitations or any other difficulties coming from outside an excuse for their failure to live up to the professional ideal The greater the difficulties, the greater the need to be on guard Some at least of the grumblings which are heard about the effect of the Welfare State and of the National Health Service on standards of professional work are to be deplored as excuses for professional shortcomings and the yielding to commercialism

Civil Servants and other administrators are often regarded by the professions as a sore trial, and sometimes with good reason , but this in fairness must be said The Civil Servants and the officials concerned with the health service have had a very difficult task placed upon them Much of their resistance to decentralisation and many of their regulations restrictions, and attempts at standardisation are not the outcome of their desire to build little empires but are forced upon them by the Legislature's insistence on continuous Parliamentary oversight not only of the policy but of the details and daily operation of the health service What would be said if the directors of a company had to meet the shareholders in almost continuous session throughout the greater part of the year and satisfy them on all the details of the company's activities ? The arrangement would be regarded as unworkable and intolerable and yet the position is not very different with the health service So let us, *at least occasionally*, spare a silent tear for the officials , they have their problems too

Conditions under Professional Control

Professor Toynbee in his recent Reith lectures on the B B C compelled his listeners to consider how *other peoples viewed the past actions of our own nation and of other nations of the West* It is painful but salutary to realise that civilising missions undertaken from high motives may be regarded by those to be civilised as acts of aggression If only to ensure their continuance in the

overworking I doubt if the authorities or the public yet see clearly the potentialities of medical social work Hence the confusion, the excessive specialisation that is becoming burdensome, the perfunctory performance by the authorities of fine sounding declarations of good intentions About a week ago a former junior Minister, in a letter to the *Times*, stated that "if the hospital is to be of the greatest value to the community it must be enabled to use modern techniques fully" By modern techniques he meant new boilers and other heating appliances, sanitary arrangements, laundries, and like items of capital equipment, and he argued for larger expenditure as the road to real economy Of course the things he had in mind are important, but better far would be the full development in the health service of the modern technique of medical-social work That is the way to better value for money, to "real economy," and perhaps in time even to a decrease in total expenditure on the service On the one hand are the opportunities to protect ex-patients of hospitals against avoidable loss of benefit received by them from costly hospital treatment Such early studies as have so far been made give a depressing picture of the number of people who a few months after leaving hospital seem no better for the treatment they received On the other hand is the vast work of lessening the need for hospital care by wise guidance of individuals at the right time The early work by almoners and others with the elderly gives foundation for high hopes of what could be achieved

Before these promising fields can be cultivated better, the professions concerned with medical-social work, in coöperation with the authorities need to clear up the developing chaos of types and different qualifications of medical social workers Much has already been spoken on this topic and I need not add to the spate of words but will wait expectantly for the introduction of the all-purposes medical social worker

Opportunity—or Frustration ?

There is a prima facie case that broadly the provision for the medical care of the population is better than it was, and that it could be better still, even within the present framework and under the present "ceiling" of financial resources, if the professions responsible for its operation and their members so determine

Conditions under Professional Control

Professor Toynbee in his recent Reith lectures on the B B C compelled his listeners to consider how other peoples viewed the past actions of our own nation and of other nations of the West It is painful but salutary to realise that civilising missions undertaken from high motives may be regarded by those to be civilised as acts of aggression If only to ensure their continuance in the

to the view that the existence of private practice is the only safeguard against a lowering of professional standards While accepting that the professions number among their members people of the highest ability and finest quality, the professions do not, so it seems to me, have a monopoly of the ablest and most admirable personalities Far from thinking that the right course for the professions is to parade themselves before the world as the best people, I believe that the wiser course will be for them to give daily evidence from the way they conduct themselves that theirs is an element worth perpetuating and strengthening

Wilfred Trotter in his *Instincts of the Herd in Peace and War* wrote

> " prodigies of genius have been expended in obscuring the simple truth that there is no responsibility for man's destiny anywhere at all outside his own responsibility, and that there is no remedy for his ills outside his own efforts "

Is not a like simple truth applicable to the professions in the health service ? They have no cause to be depressed, fearful, or of poor morale, there is more exciting and satisfying work waiting to be done by them than they can exhaust They have a great opportunity to demonstrate that the professional way of life is not defeated by changes in the public will, because the ideals towards which they strive will always serve the public good, no matter what the form or circumstances of the State may be

IMMEDIATE PRIMARY REPAIR OF SKIN DEFECTS WITH LOCAL FLAPS

C R McLaughlin
M B Camb, F R C S E
PLASTIC SURGEON, QUEEN VICTORIA HOSPITAL,
EAST GRINSTEAD, SUSSEX

In many branches of surgery the repair of skin defects constitutes a frequent and urgent problem These defects are often the immediate outcome of a planned operation, and follow an adequate excision of diseased or damaged tissue

The duty of closing raw areas as a primary procedure falls not only on the plastic surgeon but also on those working in other branches of surgery No-one, on any later occasion, has such a good opportunity of providing skin cover as the original operator at the time of operation Sherren once wrote " Anyone who opens the abdomen should be capable of dealing with any condition he may find there " Similarly, any surgeon who finds or establishes a skin defect at operation should be capable of dealing with it

In this paper emphasis is laid on immediate *primary* repair, and the advantages of repair with local skin flaps are indicated

DISADVANTAGES OF FREE GRAFTS

The use of free grafts is today so widely practised that this method of repair is now unlikely to be overlooked In the early treatment of burns, and in many other circumstances, it is invaluable Nevertheless, in ordinary instances of skin loss, whether surgical, traumatic, or pathological, the surgeon's thoughts should first turn not to free grafts but to local repair with pedicled and therefore living skin flaps The disadvantages of free grafts are as follows

(1) In functional areas they often lead to a disability, particularly where they lie in contact with tendons or with bone

(2) Their cosmetic appearance is seldom perfect

(3) It is impossible to use free grafts to cover grafts of other materials whether bone, cartilage, or fascia

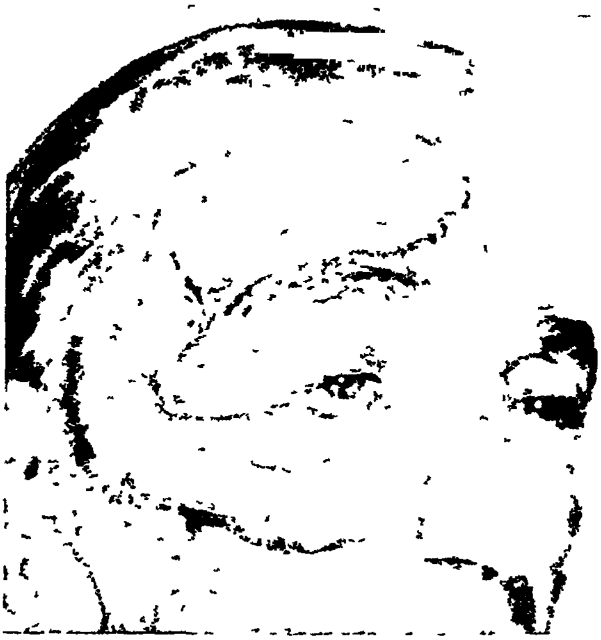

Fig 1—An Esser arterial flap used for immediate repair of lower li and cheek. This patient had multiple rodent ulceration involvin the malar bone The second stage is yet to be completed Goo function with relief of ectropion here outweighed cosmeti considerations

SKIN FLAPS FROM A DISTANCE

Flaps which have to be transported from a distance go by various names but are mainly of three kinds *direct abdominal flaps, cross leg* (and cross arm) *flaps*, and *tubed pedicles* Although the reasons for preferring local skin may appear obvious, it is necessary to consider some points relating to the use of flaps from a distance

Provided proper skin cover is afforded at the primary operation, there are certain indications for these distant manœuvres They find their best use in limb defects, where the use of local flaps is often unwise, but they are much less suited to facial defects It should be remembered that direct flaps, and especially tubed pedicles,

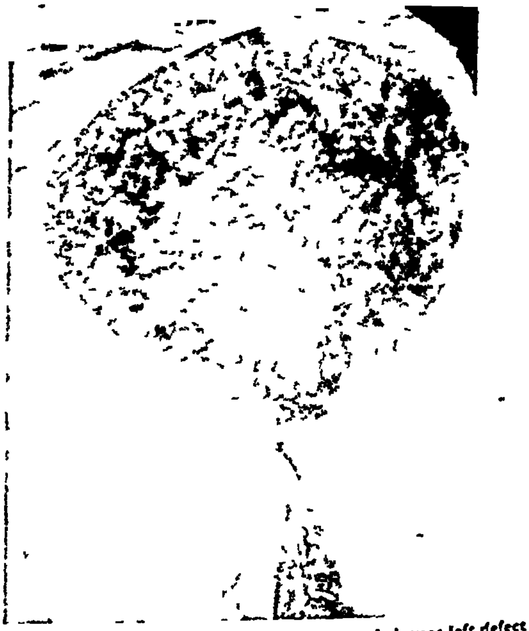

Fig 2—Adequate excision of multiple sacrococcygeal sinuses left defect 6 in in width This type of lesion is best closed by lateral sliding flaps, using Oldham s method of suturing Patient fully healed in 14 days

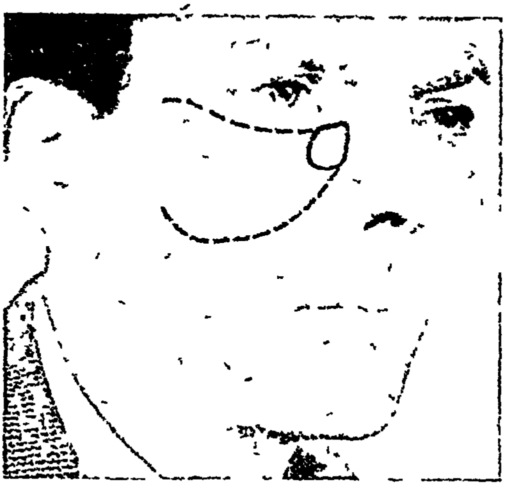

Fig 5—Repair of recurrent rodent ulcer after unsuccessful irradiation, base unsuited to free graft. Imre advancement flap must be generously designed in relation to defect. Note complete absence of ectropion after operation

1 5 to 1, but there are many exceptions, particularly on the face

The last but least defined factor is the blood supply There are no exact rules or mathematical criteria to guide the surgeon in assessing this vital issue Though it may ultimately be a matter of experience and even common sense, certain points should be appreciated

(1) The venous outflow through the base of the flap is just as important as the arterial inflow

(2) The normal vascularity of certain areas is notoriously poor—e g, the ankle, and in other sites the vascular pattern may be unfavourable, as in crossing the midline of the abdomen

(3) Very thin tissues like the eyelids, though highly vascular, are extremely susceptible to injury by careless handling

It should be pointed out that, whereas thick flaps may carry much fat, which in terms of blood supply is parasitic, very thin flaps are easily bruised and may suffer marginal thrombosis The important subdermal plexus lies in immediate contact with the under surface of the dermis, but clumsy or excessive thinning of a flap can nevertheless do unseen damage with dire results

The safest design is the arterial (or Esser) flap (fig 1) These flaps are based on a known artery—e g, the superficial temporal—and in selected cases they may be designed with a length/breadth ratio of 6 to 1 Unfortunately they cannot often be used thus, but they emphasise the principle of making the best use of the precise anatomical pattern of the adjacent vessels

Technique

The first rule of skin flap surgery is "avoid tension" It is tension which causes ischaemia, kinks the base and retards the venous return, makes sutures cut out, and results in permanent distortion The whole aim of the operator should be towards so disposing the tissues that the flap lies naturally, without either causing or suffering distortion

Flap operations do not create new skin, they simply shift it to suit the exigencies of the situation If there is no skin "reservoir" at hand, there may be a secondary defect which must always be grafted

The handling of vulnerable skin flaps demands not so much special methods as special standards Surgeons do not generally treat the abdominal skin edges with the same meticulous care that they reserve for a gastric anastomosis But any surgeon who attempts reconstruc tion with skin flaps must exercise a degree of gentlene usually associated with eye surgery Fine skin hooks, sharp needles silk sutures of minimal calibre, and the avoidance of all crushing and pulling of the skin margins—these are the simple but imperative requirements of plastic surgery

TYPES OF FLAP

The standard classification comprises sliding, advanc ment, rotation, and transplantation flaps Many surgeo will also be familiar with the double transplantatio flap, or Z-plasty, this, however, should seldom, if eve be used to close skin defects, though it remains the ide method for releasing the linear pull of a webbed an contracted scar These five varieties should be regarde merely as convenient labels and not as rigid division In any case certain designs, such as the Imre flap, d not fit exactly into any one category

The *sliding flap* is the simplest of all designs and wa described (though probably not invented) by Celsu in A D 30 It has the widest sphere of use, but depend on careful and *generous* undermining of the adjacen skin Its basic function is to convert an ellipse, wit sides of equal length, into a linear scar (fig 2) It is no intended as a euphemism for the common practic of dragging skin edges together under tension

Advancement flaps are rarely used in their pure form The case illustrated (fig 3) is a reasonably true example

Rotation flaps are particularly useful in the repair o scalp defects, in the closure of decubitus ulcers, and in a great variety of lesions of the face and trunk (fig 4) A scalp rotation flap may also be used, often on a generous scale, to close a raw area after a radical excision in the region of the ear

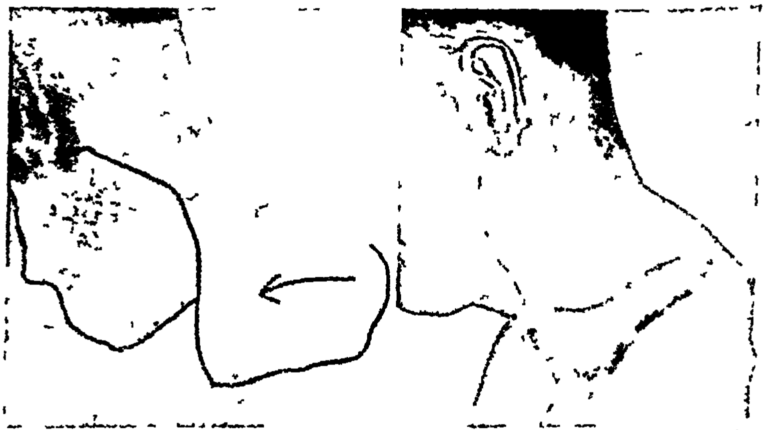

Fig 6—Epithelioma of neck extending down to carotid sheath A large transposition flap from the shoulder was used for immediate repair

Imre (1928), of Budapest, developed a flap which embodies elements of advancement as well as rotation It achieves its best results in the region of the lower eye lid, acting as a wedge which increases the amount of skin (measured vertically) and thus preventing ectropion (fig 5)

Transposition flaps are taken in most instances from the forehead or the neck, they are transposed over intervening normal tissue to reach the defect They are the basis of the forehead (Indian) rhinoplasty, though here a second stage is nearly always needed to return the base of the pedicle to its original site In the case of repairs to the lower half of the face, the neck offers the best "reservoir" of skin (fig 6) This latter type of flap has been greatly developed in recent years, and the scope of its many variations is now considerable

SPECIAL AREAS

The problems of scalp closure were concisely reviewed in 1944 by Sir Harold Gillies He laid stress on the s called upon to perform now and so far as can be foreseen in the generation ahead. Otherwise there is an abuse of the privilege of professional self-government. Admittedly on any issue there may be a difference of opinion about what is reasonable, but the obligation s on each profession honestly to look at its requirements rom the standpoint of the public as well as that of the profession, to consider confidently and without fear well-substantiated criticisms, and to justify its decisions by results. The insistence by a profession on entrance requirements markedly out of touch with the qualities and qualifications demanded by the work to be done by members of the profession entitles the community to take steps to have its needs met in other ways. If these steps lead to the substitution of other groups of workers for those of the profession, the profession has no real cause for complaint about infringement of its privileges or about dilution. The profession and its privileges exist solely to serve the public need. Any profession which has established itself securely in the public's respect will not quickly lose that respect; but it may sink in the public's estimation if it should ever appear, pigheadedly, to be setting professional advancement or administrative convenience before the public interest.

Although the cost to the State in training grants may be unnecessarily greater, little objection to the enforcement by a profession of severer entrance requirements is likely to be heard if the profession has plenty of candidates and the number admitted maintains a total supply of practitioners adequate to the work which can be undertaken with the resources the community makes available. But if the opposite is the case, what then? A clear-cut answer is difficult. Consider, for example, the serious shortage of dentists. Despite the quite high level of remuneration, dentistry does not appeal to enough young people or their parents. The profession, nevertheless, has been striving to raise the standard of qualification. The quality of the training in the dental schools has improved and a larger number and proportion of students are taking a university degree. In defence of the raising of entrance qualifications it is claimed, with some force, that this step is necessary if the prestige of the profession is to be increased sufficiently to attract more candidates. The profession seems right in this contention; but two corollaries follow.

The first is that while the profession pursues its aim, it must be careful not capriciously to oppose means of increasing the effectiveness of its existing membership. The proposal at present before the profession for the training of dental nurses to assist dentists as other nurses assist doctors is a case in point. Is there really any substance in the argument which has been voiced that such a development would lower the status of the profession? Has the skilled assistance of nurses in technical procedures lowered the status of doctors?

Simplification of Training?

The second corollary concerns the length of the training. A profession, in my submission, is in duty bound to seek ways of bringing students to the desired standard of efficiency and maturity in the shortest possible time —as was done, for instance, during the war in the training of men and women for the fighting forces and for war production. Little seems to have been published about the methods which were introduced at that time, but some of the apparently striking results give ground for thinking that a like process in the simplication and speeding up of training might with benefit be applied to some aspects of professional training in peace-time. The dental profession might well call in some of those who studied these problems during the war and give them the chance to experiment.

Some of the other professions might well do likewise. Over five years ago the Working Party on the Training and Recruitment of Nurses came to the conclusion that the basic training for nurses could without any lowering of standards be given in two years. The length of the prescribed course still remains at not less than three years. Recent evidence adds weight to the view that nurse training has got badly out of touch with the demands of the job. If it be correct that the end-result of nurse training, under present conditions, is administration and not nursing, and that in the main the rôle of nursing is being filled by people who have not yet qualified for admission to the profession, a radical overhaul is overdue. May we hope that some unfettered educational experiments, accompanied by experimental changes in the organisation of nursing, will be tried? The nursing profession will yet further strengthen its hold on the public's affection and goodwill if it tackles this difficult problem with determination and promptitude.

Duty to the Public

Man's powers being limited, it is perhaps fortunate for him that many of his problems break down into the consideration of whether he should do a little more or a little less, whether he should go a little faster or a little slower in a given direction. Implicit in what I have already said and in what I have yet to say is the plea not for something completely and radically new, but for a little more of some good things. With a sense of public duty the professions assume some responsibilities for the professional conduct of their members; my plea is that they should extend their responsibilities in this respect. They have all striven to achieve entrance requirements which will ensure recruits of the best quality; my plea is that, in their own interests and those of the public, they should be still more self-critical. And so with my last plea, which is that the professions in the health service should assume more corporate responsibility in the exercise of their self-governing powers, for the effectiveness, economy, and humanity of the medical care which coöperatively they provide.

Situation of Professions in the N.H.S.

Generally speaking the professions engaged in the health service have been well treated. For the professional freedoms of the older-established professions there has been the tenderest of regard. Whatever dangers, present or future, there may be of restrictions on these freedoms —freedom can never be free from such dangers—up to now there has been no impairment of them by the health service. On the contrary, in so far as the influence of the professions is if anything stronger than it was, the defences of the professional freedoms may also be stronger.

As regards remuneration and conditions of service, most of the professions do not seem to have much cause for complaint. For the great body of the members the financial rewards are higher than before the National Health Service, and no evidence appears to have been published establishing convincingly that the load of work falling on them individually is heavier; in some professions it seems to be less. It is no doubt true—indeed it would be surprising if it were not so—that in "real" as opposed to money terms professional members of the health service are not better off than before the war. But if this be their state, they are suffering from ills which afflict no less the other professions and the vast majority of the population. The general medical practitioners are relatively better off than the members of other professions in so far as in no other profession have earnings been increased to offset the rise in the cost of living since 1939—as has been done for them under the Danckwerts award.

The almoners have not fared as well as the rest either in pay or conditions of work. Be it said in their honour that their professional code has led them, despite official neglect, to do their utmost even at the cost of gross

POLYCYTHÆMIA AND ERYTHRÆMIA TREATED WITH PARA-HYDROXYPROPIOPHENONE*

E HAYNAL
M D
DIRECTOR, SECOND MEDICAL CLINIC, UNIVERSITY OF BUDAPEST

F GRÁF
M D

E MATSCH
M D

THAT overactivity of the pituitary-hypothalamic system can be demonstrated in symptomatic polycythæmia and erythræmia was shown by Haynal and Gráf (1950), who tried to reduce the pituitary function by giving sex hormones, vitamin B_1, and radiotherapy without, however, obtaining decisive results

Lacassagne et al (1951) and Desclaux et al (1952) reported the pituitary-depressant property of *p*-hydroxypropiophenone, which produced histological changes in the ovaries, testes, seminal vesicles, and prostate, and they attributed these changes to decreased secretion of the luteinising hormone They also showed that the secretion of thyrotropin and somatotropin was decreased

Perrault and Vignalou (Perrault and Vignalou 1949, Perrault 1950, 1951) used *p*-hydroxypropiophenone with satisfactory results in all those forms of hyperthyroidism in which the excessive production of thyrotropin plays an important part They got the same good results in hyperfolliculinæmia due to overaction of the follicle-stimulating hormone They could not establish any depressant action on the secretion of the adrenocorticotropic hormone (A C T H) Guillemin (1951) and Hertz and Tullner (1951) could not confirm these findings, nor could Netter et al (1952) find any depressant action on the secretion of the pituitary gonadotropic hormone None of these workers observed any effect on the erythropoietic system or on the blood

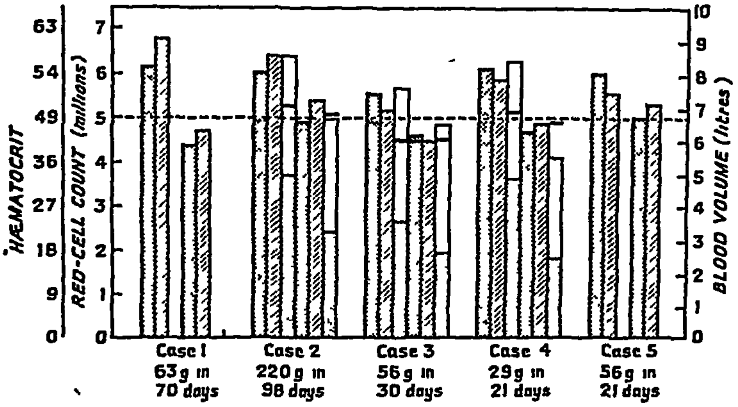

Fig 1—Findings before and after treatment in symptomatic pituitary polycythæmia

▯ Plasma
▯ Red cells
— Normal blood volume calculated from body-weight

Key to figures

For these reasons we tried this new pituitary-depressant, *p* hydroxypropiophenone, in four cases of symptomatic polycythæmia and nine cases of erythræmia The treatment of five of the cases of erythræmia had unfortunately to be stopped because of temporary lack of *p* hydroxypropiophenone We studied the clinical signs and symptoms, the blood-pressure, and the hæmatology, including the bone marrow picture, and we made the usual laboratory tests of the function of the pituitary, thyroid, adrenals, liver, and kidneys

The clinical and laboratory findings are summarised in the accompanying table and figs 1–3 The table contains some clinical and laboratory findings before and after treatment Fig 1 shows the red cell counts, hæmatocrit values, and blood volume of the patients with symptomatic pituitary polycythæmia, fig 2 those of patients with erythræmia who received full treatment, and fig 3 those of patients with erythræmia whose treatment had to be stopped because of temporary lack of *p*-hydroxypropiophenone

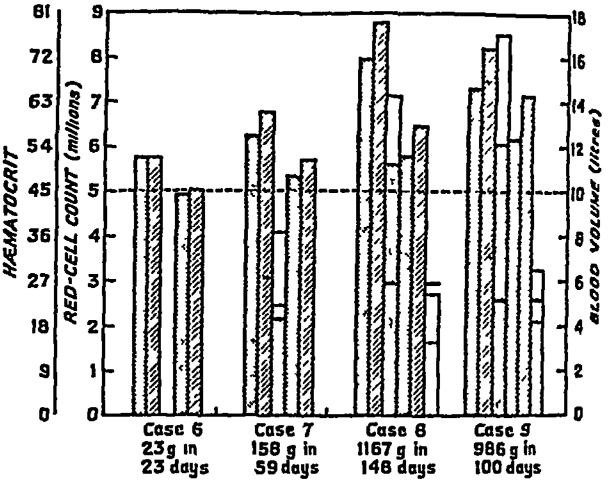

Fig 2—Findings before and after treatment in erythræmia

MATERIAL

Cases 1 and 2 had hyperpituitary obesity (principally on the face, neck, and trunk, the extremities being less affected) with high blood pressure but without changes in the sella turcica, striæ, osteoporosis, ocular manifestations, or enlargement of the spleen They may have had Gaisbock's disease (polycythæmia hypertonica) Case 3 was an obese young girl with diabetes mellitus and symptomatic polycythæmia Cases 4 and 5 were two treatments in one and the same acromegalic giant without hypertension or enlargement of the spleen Case 10 probably had Gaisbock's disease and was slightly acromegalic, with a normal sella, no ocular changes, a normal spleen, and moderate hypertension All the other patients had erythræmia

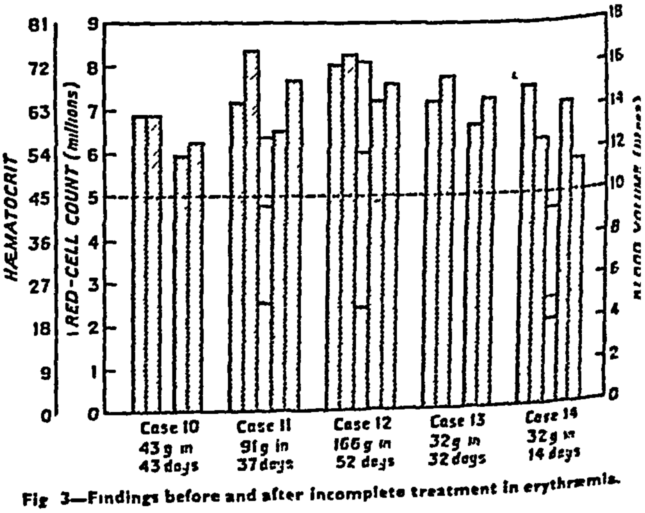

Fig 3—Findings before and after incomplete treatment in erythræmia

public's good graces and thus to safeguard their freedoms, the professions in the health service might be well advised to try more frequently and openly to put themselves in the place of the client and attempt to understand what he feels about their ethics and practices. In moments of idle speculation I have toyed with the notion that the professional members of the health service might be assisted in such an attempt if they adopted the convention that any medical treatment or care they needed for themselves or their relations should be received only as ordinary patients of the health service under the same conditions as the ordinary patients.

---

*Based on a paper read at a meeting of the medical section of the Hungarian Academy of Sciences in Budapest on June 30, 1952

A few weeks ago the Central Health Services Council issued a memorandum on the Reception and Welfare of Inpatients in Hospitals. No-one is likely to contend that any of the recommendations in that memorandum was unreasonable or unnecessary. The conditions and practices which, in the mildest language, the council seeks to change are not the product of misguided decisions of Ministers of the Crown or of unfeeling Civil Servants. They are the product of the past practices and attitudes of hospital staffs—of members of honoured professions. The Central Health Services Council cannot be described as an ignorant or unsympathetic or revolutionary body. That it has considered the publication of this memorandum to be necessary reflects upon the professions which run the health service and should give cause for heart-searching. In a service staffed by professional people should it be necessary to include among the main recommendations statements such as these ?:

> "In all their dealings with patients and their relatives, members of the staff should find time to show consideration and understanding of their point of view."
>
> "Reception arrangements should ensure that the patient is looked after quickly and sympathetically."
>
> "Meal times should be spaced so that patients have no long fasts."
>
> "Patients should not be wakened earlier than 6 A.M., and later if possible."

Platitudes ? Well maybe ; but platitudes important to a fearful or pain-racked patient and his anxious relatives. It is within the power of the professions to put these recommendations into effect forthwith.

The hospital of today is a complex and highly technical organisation, but its chain of responsibility is too often anarchic. It might be compared to a medieval army which unlike the army of today was not an integrated organism but an aggregate of independent knights each with his squire (or registrar) and his followers. Though bound together vaguely by a common purpose, each knight was independent and free to do much as he pleased. Such analogies must not be pressed too far, and there is much that is right in the doctor's insistence that he must be allowed to do his work in his own way. But I suggest that some collective responsibility should be accepted by the clinicians in association with the other professional workers in each specialty for the service that is given to the population, and that they should consider it their duty so to arrange their work as to make the best possible use not only of their own skill but of the facilities of the hospital. There is some evidence for suggesting that they could do much to improve the arrangements for outpatients and also that by operating a more flexible allocation of beds to different specialties they could greatly reduce waiting-lists without any increase in the total number of beds.

Medical Leadership or Medical Domination ?

This question is not one solely for the medical profession. As the profession with the duty of leadership, it has the heavier responsibility, but all the professions are involved. Given true leadership, in place of domination, by the medical profession I feel little doubt that the other professions would increasingly make their contributions; and valuable contributions they could be.

At this stage it is necessary to refer to the relations between the various professions. Here I find myself at variance with a view which is sincerely held, I believe, by quite a number of admirable doctors and which seems to have been the view of those who signed the majority reports of the Cope Committee on Medical Auxiliaries—namely, that members of the non-medical professions are the servants of doctors, their inferiors and subordinates, in whose occupational organisations and affairs medical opinion should predominate. It is not disputed that upon the medical profession and upon the individual doctor falls the duty of leadership. In the care of an individual patient, the doctor is and must be the leader of the team, and those working with him must loyally comply with his decisions and instructions ; but if he is a real leader he will, in reaching his decisions, have distilled his own and his colleagues' knowledge and experience. And so it should be in the relations of the medical profession and the other professions in the health service. The clue is in the word "colleague," and here I turn again to Dr. Fox's Croonian lectures. In considering the problems arising between members of the medical profession engaged in group practice or in team-work in hospital he said :

> ". . . all are colleagues, not inferiors or superiors. If we want freedom *for* the profession, we must cherish freedom *within* the profession. The colleague is a responsible person, whereas the subordinate is not ; and responsibility is the best known means of evoking effort."

You will note the last words. Believing that experience shows them to be true, I should respectfully add to Dr. Fox's statement that if the medical profession desires freedom for itself and the fullest and best help from the other professions—without whose devoted and loyal assistance it cannot give proper medical care to its patients—it should cherish freedom not only within its own profession but *for* and *within* those other professions, regarding those other professions as its valued colleagues.

Old Attitudes or New ?

The recommendations of the Central Health Services Council touch also upon the question of those attitudes and practices of members of the professional staffs of hospitals, to which there is reason to think objection is taken by an increasing number of patients. These are practices which by the wildest stretch of the imagination cannot be regarded as an essential of medical care. Those which evoke the strongest adverse comment are by no means general. In many cases, I am quite sure, those guilty of them are not so by deliberate intent —indeed are not conscious that they are acting in an objectionable manner unbecoming to a professional man or woman. The trouble is that the professions grew accustomed to these attitudes and practices in the days before hospitals became national institutions serving all sections of the population ; they have become accepted or tolerated without protest by the professions with the result that they are thoughtlessly adopted by some as normal conduct. Stories of discourtesy are too persistent and widespread to be ignored and are damaging to the good name of the professions. Sometimes it is little more than a thoughtless attempt to make the patient fit the rule.

Within all professions there are strong herd feelings. It is to be hoped that the professions will look at their unwritten codes of what is and what is not done and use herd opinion to encourage improvements in conventional habits and attitudes of their members.

It will, I hope, have become clear that, while agreeing with much that they have written, I take a somewhat different view of the professions from that of Lewis and Maude in their recent book *Professional People.* While I believe that the professions at the present time are a most valuable element in social life, I cannot subscribe

DOSAGE

At first we used the "higher" doses of the French workers—i e, 0 5–1 0 g daily Later we increased the dosage to 3 or 4 g daily and in our last patients to 8–12 g daily This increased dosage was necessary because it proved to be in some cases the only efficient one We dared to increase it because the lower dosage was smaller than that usual in experiments on animals The dosage for a man weighing 60 kg would be 36 g per day calculated from the dosage used in animals (40 mg daily in mice and 120 mg in rats—i e, 0 6 g per kg body-weight)

RESULTS

In two cases there were undesirable effects nausea and vomiting in case 14, and toxicoderma in case 13 Since we had to stop the treatment in both cases owing to lack of *p* hydroxypropiophenone, these effects disappeared rapidly

The *red cell count* and the *hæmatocrit* value decreased in most of the cases of symptomatic polycythæmia in response to a small total dosage of 23–63 g (cases 1, 3, and 4) and in one case of erythræmia (case 6) Most of the cases of erythræmia (cases 7, 8, and 9) and one of symptomatic polycythæmia (case 2) needed a much higher dosage (158–1167 g) Four of the cases which could not be completely treated through lack of *p*-hydroxypropiophenone reacted well to a small dosage, and the fifth (case 12) only to a larger one

The treatment lasted 21–148 days A quick result could not be expected, because the decrease of the red cells due to the depressant action of *p* hydroxypropiophenone on the pituitary must be a slow process and cannot be expected until some time has elapsed The blood volume of those fully treated patients who were checked in this respect (cases 2, 3, 4, 8, and 9) decreased to normal, principally owing to the decrease of the red cells and, to a lesser degree, to that of the plasma (figs 1 and 2) The characteristic external appearance of the patients disappeared more or less pari passu with the hæmatological improvement

The *body-weight* of five patients diminished during treatment the pituitary obese (case 1) lost 12–13 kg, and the pituitary giant (case 4) lost 6 kg The patients with erythræmia generally maintained their weights, except two, one of whom lost 3 kg (case 8), the other 1 kg (case 14) The decrease of the body weight was not due to increased excretion of water One patient with erythræmia (case 9) gained 2 kg during treatment

The *spleen* in three patients (cases 6, 8, and 9) diminished considerably The *blood-pressure* of four patients (cases 1, 2, 7, and 10) fell during treatment

The *bone-marrow* picture was generally hypoplastic with preponderance of the erythropoietic system over the granulopoietic one (1 1 instead of $^{1}/_{3}$–$^{1}/_{4}$ 1) The bone-marrow picture did not alter essentially during treatment, there was no conspicuous morphological change in the maturation or proliferation of the cells, and signs of intoxication of the erythropoietic system (toxic granulation, vacuolisation, pyknosis) were absent There was probably a slight alteration in the ratio of the erythropoietic and granulopoietic systems at the expense of the former

Nothing that could have pointed to increased hæmolysis during treatment could be established, the serum-bilirubin and urine-urobilinogen levels did not increase, nor did the osmotic resistance of the red cells diminish There was no change in the reticulocyte-count, which was rather low (4–5%) and pointed also generally against the possibility of increased hæmolysis

Liver-function tests (thymol turbidity and goldsol reaction) and examinations of *urine* did not show any change either

The *B M R* of four patients (cases 7, 8, 9, and 11) decreased slightly, that of one patient (case 1) increased moderately, and that of six patients did not alter The *serum cholesterol* levels were raised, thus indicating the same change of thyroid action From these findings we dare not form any opinion on the change of thyroid function, further investigations of the serum protein bound iodine will have to decide the question

The changes in the *serum-potassium* and *serum sodium* levels and urinary excretion of *17 ketosteroids* were not great enough to allow any definite conclusions to be drawn The serum sodium level seemed to fall, if that were true, it would point to a diminution in the secretion of the mineralo corticoids of the adrenals The changes in urinary excretion of the 17-ketosteroids are also uncertain, but perhaps they point also to a decreasing function Further investigations are necessary to decide whether the adrenal cortical function diminishes during the treatment

No changes were found in the *sexual organs*, nor was there any change in the potency or in the libido of our patients The spermatogenesis of one patient (case 9) was impaired the sperm count was diminished (about 2,000,000 per ml), the motility was $^{4}/_{10}$–$^{5}/_{10}$, but more than half the spermatozoa were of normal structure

The *glucose tolerance* curves became flatter in only four patients (cases 1, 9, 10, and 13), one of these was the pituitary obese patient (case 1) Very probably the reason for the lack of this change in the other patients is that *p-hydroxypropiophenone depresses the secretion of only* one of the pituitary hormones acting on the carbohydrate metabolism—i e, the pituitary growth hormone —and does not depress the production of A C T H

There was no conspicuous change in the *white cell* picture

The therapeutic results were not permanent The return of the blood of the pituitary giant (case 4) to normal lasted only two months after treatment was stopped, then the red cells increased again to 6,000 000 per c mm and the hæmatocrit value to 50 5, and the patient had to undergo a second treatment, consisting of 56 g of *p* hydroxypropiophenone in twenty one days, until his values became again normal (case 5) His blood has remained normal since then with a maintenance dosage of 1 g daily Two patients (cases 2 and 6) had a relapse after two months and four and a half months respectively, their red cells increased to 5 500 000 per c mm and their hæmatocrit values to 52 and 53 respectively One patient (case 1) died meanwhile elsewhere of a perforated appendix Unfortunately we learnt too late of his death to make a post mortem examination The blood of the diabetic girl (case 3) was still normal six months after the end of the treatment, probably she will need a maintenance dosage

DISCUSSION

We introduced the treatment of erythræmia and symptomatic hyperpituitary polycythæmia with *p* hydroxypropiophenone as a result of our previous investigations (which suggested that overactivity of the pituitary hypothalamic system plays a part in the pathogenesis of these diseases) and of the discovery of French pathologists and clinicians of the depressant action of *p* hydroxypropiophenone on the pituitary So far our therapeutic results indicate the possibility of improving or bringing back to normal the blood in these diseases by diminishing the pituitary secretion without hæmolysis of the red cells or toxic effect on the bone marrow The different ways in which the two types of polycythæmias—i e, symptomatic pituitary polycythæmia and erythræmia—react point also to this pathogenesis

The depression of the pituitary activity could have influenced the blood formation either directly or through the target glands, the thyroid, the adrenal cortex, and the gonads All of them play, as experimental and public's good graces and thus to safeguard their freedoms, the professions in the health service might be well advised to try more frequently and openly to put themselves in the place of the client and attempt to understand what he feels about their ethics and practices. In moments of idle speculation I have toyed with the notion that the professional members of the health service might be assisted in such an attempt if they adopted the convention that any medical treatment or care they needed for themselves or their relations should be received only as ordinary patients of the health service under the same conditions as the ordinary patients.

A few weeks ago the Central Health Services Council issued a memorandum on the Reception and Welfare of Inpatients in Hospitals. No-one is likely to contend that any of the recommendations in that memorandum was unreasonable or unnecessary. The conditions and practices which, in the mildest language, the council seeks to change are not the product of misguided decisions of Ministers of the Crown or of unfeeling Civil Servants. They are the product of the past practices and attitudes of hospital staffs—of members of honoured professions. The Central Health Services Council cannot be described as an ignorant or unsympathetic or revolutionary body. That it has considered the publication of this memorandum to be necessary reflects upon the professions which run the health service and should give cause for heart-searching. In a service staffed by professional people should it be necessary to include among the main recommendations statements such as these ?:

> "In all their dealings with patients and their relatives, members of the staff should find time to show consideration and understanding of their point of view."
>
> "Reception arrangements should ensure that the patient is looked after quickly and sympathetically."
>
> "Meal times should be spaced so that patients have no long fasts."
>
> "Patients should not be wakened earlier than 6 A.M., and later if possible."

Platitudes ? Well maybe ; but platitudes important to a fearful or pain-racked patient and his anxious relatives. It is within the power of the professions to put these recommendations into effect forthwith.

The hospital of today is a complex and highly technical organisation, but its chain of responsibility is too often anarchic. It might be compared to a medieval army which unlike the army of today was not an integrated organism but an aggregate of independent knights each with his squire (or registrar) and his followers. Though bound together vaguely by a common purpose, each knight was independent and free to do much as he pleased. Such analogies must not be pressed too far, and there is much that is right in the doctor's insistence that he must be allowed to do his work in his own way. But I suggest that some collective responsibility should be accepted by the clinicians in association with the other professional workers in each specialty for the service that is given to the population, and that they should consider it their duty so to arrange their work as to make the best possible use not only of their own skill but of the facilities of the hospital. There is some evidence for suggesting that they could do much to improve the arrangements for outpatients and also that by operating a more flexible allocation of beds to different specialties they could greatly reduce waiting-lists without any increase in the total number of beds.

Medical Leadership or Medical Domination ?

This question is not one solely for the medical profession. As the profession with the duty of leadership, it has the heavier responsibility, but all the professions are involved. Given true leadership, in place of domination, by the medical profession I feel little doubt that the other professions would increasingly make their contributions; and valuable contributions they could be.

At this stage it is necessary to refer to the relations between the various professions. Here I find myself at variance with a view which is sincerely held, I believe, by quite a number of admirable doctors and which seems to have been the view of those who signed the majority reports of the Cope Committee on Medical Auxiliaries—namely, that members of the non-medical professions are the servants of doctors, their inferiors and subordinates, in whose occupational organisations and affairs medical opinion should predominate. It is not disputed that upon the medical profession and upon the individual doctor falls the duty of leadership. In the care of an individual patient, the doctor is and must be the leader of the team, and those working with him must loyally comply with his decisions and instructions ; but if he is a real leader he will, in reaching his decisions, have distilled his own and his colleagues' knowledge and experience. And so it should be in the relations of the medical profession and the other professions in the health service. The clue is in the word "colleague," and here I turn again to Dr. Fox's Croonian lectures. In considering the problems arising between members of the medical profession engaged in group practice or in team-work in hospital he said :

> ". . . all are colleagues, not inferiors or superiors. If we want freedom *for* the profession, we must cherish freedom *within* the profession. The colleague is a responsible person, whereas the subordinate is not ; and responsibility is the best known means of evoking effort."

You will note the last words. Believing that experience shows them to be true, I should respectfully add to Dr. Fox's statement that if the medical profession desires freedom for itself and the fullest and best help from the other professions—without whose devoted and loyal assistance it cannot give proper medical care to its patients—it should cherish freedom not only within its own profession but *for* and *within* those other professions, regarding those other professions as its valued colleagues.

Old Attitudes or New ?

The recommendations of the Central Health Services Council touch also upon the question of those attitudes and practices of members of the professional staffs of hospitals, to which there is reason to think objection is taken by an increasing number of patients. These are practices which by the wildest stretch of the imagination cannot be regarded as an essential of medical care. Those which evoke the strongest adverse comment are by no means general. In many cases, I am quite sure, those guilty of them are not so by deliberate intent —indeed are not conscious that they are acting in an objectionable manner unbecoming to a professional man or woman. The trouble is that the professions grew accustomed to these attitudes and practices in the days before hospitals became national institutions serving all sections of the population ; they have become accepted or tolerated without protest by the professions with the result that they are thoughtlessly adopted by some as normal conduct. Stories of discourtesy are too persistent and widespread to be ignored and are damaging to the good name of the professions. Sometimes it is little more than a thoughtless attempt to make the patient fit the rule.

Within all professions there are strong herd feelings. It is to be hoped that the professions will look at their unwritten codes of what is and what is not done and use herd opinion to encourage improvements in conventional habits and attitudes of their members.

It will, I hope, have become clear that, while agreeing with much that they have written, I take a somewhat different view of the professions from that of Lewis and Maude in their recent book *Professional People*. While I believe that the professions at the present time are a most valuable element in social life, I cannot subscribe

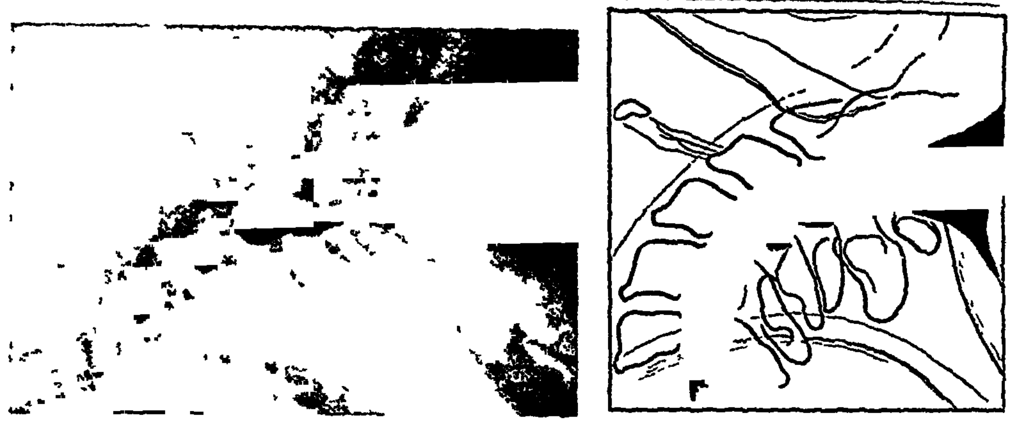

Fig 2—Myelogram of cervical spine in hyperextension in cadaver

pyramidal tracts are involved earliest and most severely, the spinothalamic tracts are implicated next, often with an ill-defined upper level, and the posterior columns either escape or show minor signs of dysfunction such as depression of vibration sense or of joint position sense at the periphery Signs of cervical root compression and symptoms referable to the neck may be absent This last and rather odd fact causes difficulty in localisation of the responsible lesion and is the reason for the frequent initial diagnosis of degenerative or demyelinating disease of the spinal cord

MECHANISM OF COMPRESSION

Kahn (1947) suggests that the ligamenta denticulata and the short transversely disposed nerve roots fix the cord forward against the disc protrusions He has charted the lines of stress thus occasioned, and shows that the main burden falls on the pyramidal, spinothalamic, and lateral spinocerebellar tracts This accords with the common clinical picture Allen (1952) has observed at operation that adhesions round the protrusions and the nerve roots fix the cord, preventing the gliding which normally takes place during cervical movement. Kinking of the cord and vessels, with resultant ischæmia, is thought to occur mainly during flexion Brain et al (1952) emphasise the formation of extradural adhesions which limit movement of the spinal cord and they mention the greater deformity occurring in extension We have observed at operation not only the extradural vascular adhesions, surrounding the nerve roots in thick sleeves, but also, in many cases, spidery intradural adhesions running from the posterior part of the cord to the dura mater at the site of the disc protrusions It has further been observed that the extradural fat on the posterior part of the dura is often scanty or absent, and that adhesions form between the dura ligamenta flava, and laminæ This is thought to furnish evidence for the posterior compressing agent to be described Bedford *et al* (1952) follow Kahn in their emphasis on the fixation of the cord by thickened ligamenta denticulata, and suggest that it is thereby rendered vulnerable to normal neck movements Bucy et al (1948) emphasise the up and down movement of the cord over the protrusion at each respiratory movement and cardiovascular pulsation Mair and Druckman (1953) have shown, in sections of spinal cord, that demyelination takes place mainly in areas supplied by the terminal branches of the anterior spinal artery They imply that diminution in the arteriolar blood-flow secondary to compression of the main vessel causes this demyelination

POSTERIOR COMPRESSING AGENT

Hitherto attention has been focused on the anteriorly placed protrusions and on the adhesions forming round them secondarily to the venous congestion and serous exudation which they are presumed to cause Evidence is presented here for the important intervention of structures lying posterior to the cord—the ligamenta flava

It has previously been shown (Taylor 1951) that, when the neck is hyperextended, the ligamenta flava are compressed between the adjacent laminæ to form bulges which project forward into the spinal canal Figs 1 and 2 show tracings of a column of oil in the cervical canal with the neck in the neutral position (fig 1) and after forced hyperextension (fig 2) It can be seen that in hyperextension the ligament projects about a third of the way across the canal In a normal person this is of no importance, because the spinal cord can move forward towards the anterior wall of the canal and escape damage If there is a protrusion on the anterior wall, the cord will be compressed between the two projections when the neck is extended Fig 3 shows a column of oil in the cervical canal compressed in this way in a cadaver and fig 4 shows complete interruption of the column in a living person whose symptoms were later relieved by operation

From previous writings a considerable volume of evidence can be obtained in support of this conception Morton (1936) described a case of spondylitis deformans, with compression of the spinal cord, in which the symptoms were more pronounced on extension of the neck This movement also

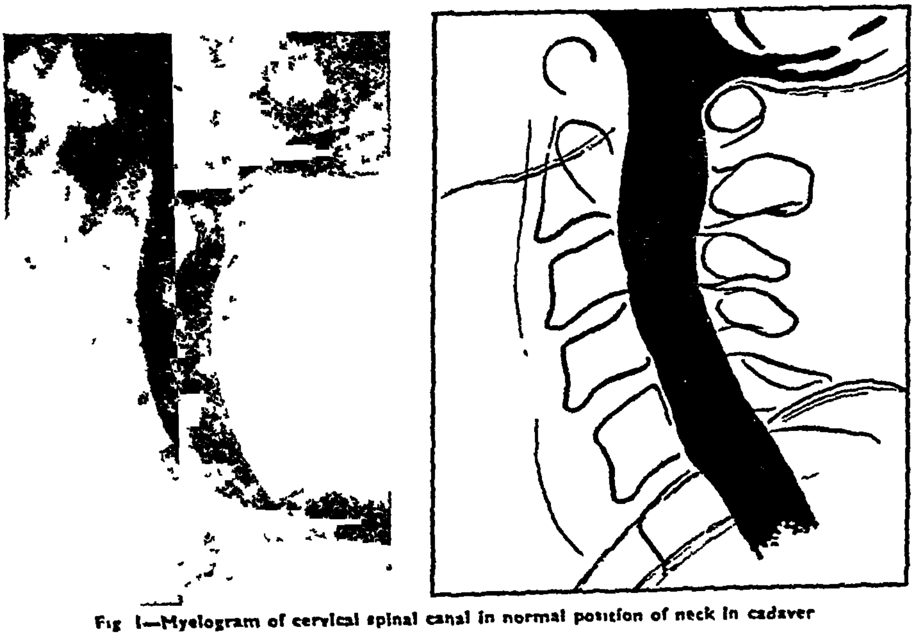

Fig 1—Myelogram of cervical spinal canal in normal position of neck in cadaver

are peculiarly vulnerable to infection if applied to granulating wounds. Also the usefulness of cross-leg flaps in operations for primary wound closure is governed by the necessity, in most circumstances, for a preliminary "delaying" operation.

As regards the tubed pedicle, it must be frankly admitted that ever since its invention in 1917 it has exercised an undue fascination. Its novelty, its vitality, and its astonishing migrations have lured some unsuspecting surgeons into grave trouble. There is, of course, no difficulty whatsoever in raising an impressive tubed pedicle; but to complete the necessary four or six stages is often risky, tedious, complex, and disappointing. Elaborate tests designed to expedite these stages and to ensure safety do not remove the inherent hazards of the method. In any case the perfectly designed tubed pedicle is never available to the surgeon who, often through no lack of foresight, is confronted with a large defect in urgent need of immediate repair.

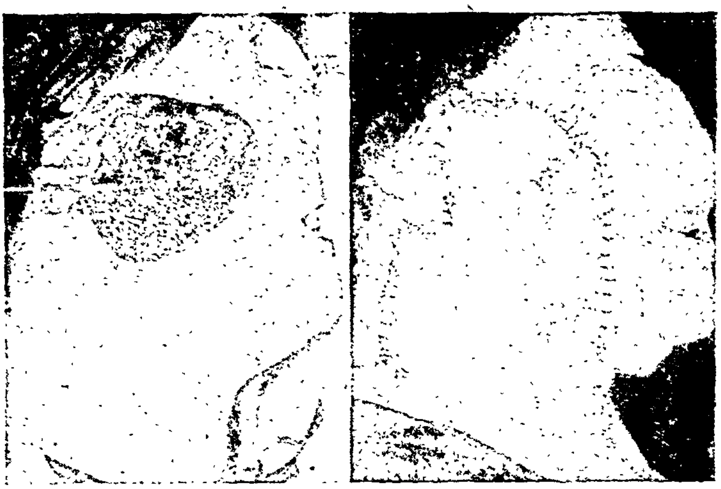

Fig. 3—Excision of fungating rodent ulcer involving parotid in patient aged 80. This might be repaired by a split skin graft, but a neck flap gives a more satisfactory and certain result.

These arguments, however, in no way apply to the proper use of tubed pedicles in extensive and necessarily elaborate reconstructions. Criticism is here only directed against their injudicious use for repairs that can be made much more safely by simpler means.

ADVANTAGES OF LOCAL FLAPS

The primary advantage of local skin in the repair of an adjacent defect is its similarity of texture and colour. The skin of the cheek is sure to look better on the cheek than skin from the abdomen or even postauricular skin.

A second advantage arises from its accessibility; it saves a great deal of time to operate wholly in one area and not to be concerned with remote donor areas. This mainly applies to cases where local flaps leave no secondary defect; but it is not unfair to suggest that with increasing skill and experience such secondary raw areas in need of grafting are surprisingly infrequent.

Many defects produced by major excisions for malignant disease require primary skin cover with some type of local flap. The essence of the method is to achieve primary cover; and this object is fulfilled even in those patients who subsequently need a later surgical trim to tidy up an ugly redundance or to replace the base of a transposed flap.

LIMITATIONS OF LOCAL FLAPS

It should be clearly recognised that in certain parts of the body local flaps are either inadvisable or entirely wrong. Their use is slightly limited on the upper limb and distinctly hazardous on the leg. The palm, the ankle, and the sole of the foot should in most cases be prohibited areas. If local flaps are used to repair extensive lesions of the limbs, very stringent precautions are necessary.

Elsewhere difficulties are apt to arise in certain awkward and restricted sites. For example, in rodent ulceration at the inner canthus involving a portion of both upper and lower lids it is quite possible to carry out a repair using one or more local flaps of the types described by Imre (1928) and others. But it may be better surgery to use a free graft (provided there is no exposed bone), since in this site it often provides better function with a less distorted contour and allows earlier recognition of any recurrence.

Another problem arises from the presence of radiodermatitis round a previously irradiated lesion which is often the result of ill-advised treatment. This tiresome complication may restrict the use of adjacent skin flaps.

A warning must also be added on the danger of attempting to use contused, lacerated, or ischæmic skin to repair recent traumatic injuries. The necessary undermining and the inevitable postoperative œdema and tension will often suffice to kill skin which would otherwise survive. In such injuries the use of provisional free grafts is fully justified.

PRINCIPLES OF LOCAL FLAPS

The skin over most of the body is elastic, though in varying degree. Apart from its intrinsic capacity to stretch, it is also mobile and can thus be moved within limits in relation to deeper structures. Both these characteristics depend on many factors, but mainly on site and age. The scalp is inelastic and relatively immobile; by contrast the skin of the neck, especially in the aged, is remarkably adaptable.

Though a large flap tends to be less vulnerable than a very small one, the question of shape is much more significant. The important point is the ratio of length (base to apex) compared with breadth. It is usually taught that this ratio should in general not exceed

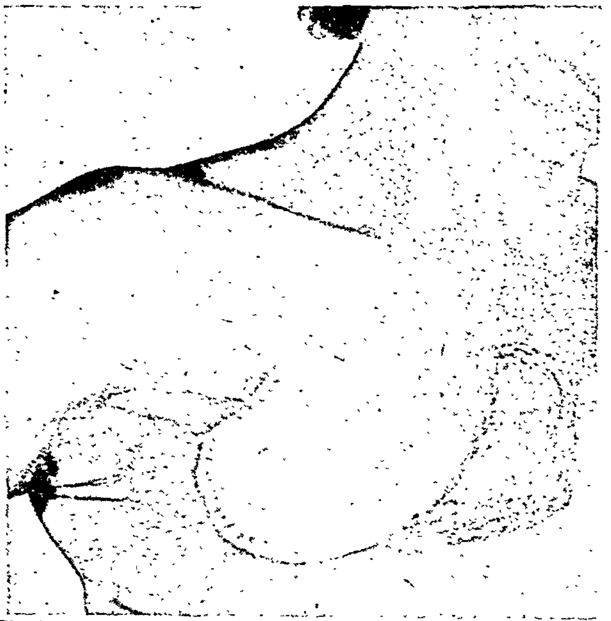

Fig. 4—Ten years after a radical excision for carcinoma of breast this patient had a recurrence involving two ribs. Excision down to pleura left a defect best closed with a rotation flap. Patient free from trouble 21 months later.

It is suggested therefore that this form of treatment should be reserved for patients who are physically unfit for operation A trial period of conservative treatment is illogical Some improvement may take place but it does not warrant the postponement of surgical relief

Posterior spinal fusion may bring permanent relief by immobilising the ligamenta flava, but as a mechanical solution of the problem it has less to commend it

Surgical measures so far described are laminectomy, removal of periradicular adhesions, division of ligamenta denticulata, and removal of disc protrusions Opinions differ about the advisability of removing hard bony ridges from in front of an adhering theca and spinal cord Allen (1952) describes his own technique for their eradication Brain et al (1952) advance considered reasons for holding removal to be dangerous and unjustified If removal can be safely accomplished it would clearly be a considerable mechanical gain for the spinal cord, but it must be a matter for each surgeon to decide in the light of his own experience The author's present and tentative opinion is that where the compressing agent is a nuclear protrusion—15% of a recent series in Edinburgh—it should be removed Where a bony ridge composed of ossified annulus and osteophytes is found it should be left undisturbed The following measures are available to ensure that it no longer fixes or causes compression to the spinal cord

Approach is by laminectomy and removal of ligamenta flava *It is not enough to make a window in the adjacent laminæ, leaving the ligaments and their attachments relatively undisturbed It should, however, be sufficient* to remove one lamina with its two attached ligaments for each anterior protrusion There is an advantage in conserving laminæ, for spinal stability, and it does not seem necessary to remove two routinely, as is usually suggested An exception might be made where the anterior bar is unusually high, requiring a greater degree of posterior decompression

Vascular extradural tissue surrounding roots and dura is systematically coagulated and removed thereby mobilising the theca

If the roots are raised and compressed against the articular facets the borders of these are trimmed to widen the *intervertebral canals* The least traumatic method of doing this is to grind down the bony shelves with a dental burr until there remains only a thin layer of cortical bone which can be picked off with fine rongeurs or a blunt hook Any cutting instrument inserted below the bone readily injures the roots How much of the articular facets may be removed without danger of later subluxation is a matter of opinion Certainly the less removed consistent with root decompression the better

The dura is opened in the midline Adhesions between the cord and the dura are systematically divided Ligamenta denticulata above *and below the protrusion* or protrusions are cut It will then be found that the spinal cord is freely movable within the range determined by the intradural course of the nerve-roots

ILLUSTRATIVE CASE RECORD

A railway foreman, aged 55, came for examination in January, 1952, complaining of stiffness in the right leg for two years *The stiffness had affected the ankle first and the* hip and knee later In the last four months the left leg had become similarly affected to a lesser degree Walking was becoming very difficult and he had had to stop working He reported no previous illnesses of importance and no injuries There were no disturbances of sphincters no stiffness or clumsiness of the upper limbs and no pain in the neck or shoulders

On examination he was intellectually well preserved No abnormality was found in the cranial nerves, in particular no nystagmus or increase in the jaw jerk There was no atrophy or fibrillation of muscles *There was loss of power* in both legs greatest in ankle movement, and more in the right leg than in the left There was no loss of power in the arms or trunk *Tone was increased in both lower limbs*, in the right more than in the left Some incoördination in rapid movements of both toes and ankles was found worse on the right The gait was typically spastic, with circumduction and scuffling of the right foot Examination of reflexes showed depression of the right biceps jerk and inversion of the right supinator jerk, with associated finger flexion, increased right finger jerk, with positive Trömner and *Hoffmann* signs, bilateral increase of knee and ankle jerks without clonus bilateral absence of abdominal reflexes, and extensor plantar responses The only sensory abnormality was some loss of *appreciation of vibration over the right foot and shin*

Lumbar puncture produced clear C S F Response to jugular compression was normal in flexion and extension, and the protein content was 50 mg per 100 ml

Radiography showed narrowing of the C5–C6 interspace with pronounced formation of posterior osteophytes Myelography confirmed the presence of a ridge at C5–C6 indenting the oil column anteriorly When the neck was hyperextended the usual ligamentum flavum indentations appeared, producing a complete break in the oil column opposite the disc protrusion.

Operation was on the lines suggested above The appropriate lamina and ligamenta flava having been removed, a bony ridge was found at the point of emergency of the C6 roots, and the spinal cord and dura were freed from it

Postoperative Course—Two days later there was subjective improvement in the stiffness of the legs In fourteen days the patient could walk better, and in twenty one days he walked almost normally, with a trace of right foot drop Power in the individual muscle groups was greatly improved The reflex changes in the limbs were unchanged In five weeks he returned to work Six months later it was found that he still had some weakness of the right ankle, with a tendency for the foot to invert after walking about fifty yards Knee and ankle jerks were no longer exaggerated, *but the plantar* responses remained extensor Abdominal responses had returned on the left side but were still absent on the right There was still loss of vibration sense in the toes of the right foot only

If the patient comes to surgery before irreversible changes have taken place in the spinal cord, recovery may be fairly complete and surprisingly rapid. If he comes too late for recovery, removal of the compression will halt the onward progress of the condition

SUMMARY

The association of spinal cord disorders with cervical spondylosis is briefly reviewed The difficulty of explaining a cervical cord compression syndrome in the apparent absence of true compression is stated.

It is suggested that the ligamenta flava, bulging anteriorly in cervical extension, cause recurring trauma to the cervical cord raised upon a disc protrusion or an osteophytic bar Experimental and clinical evidence in favour of this hypothesis is advanced

Proposals for treatment are made, and an illustrative case is *described*

I wish to thank Prof Norman Dott, in whose department the work was done, for helpful criticism, Dr Robert Saffley and Mr R White, of Bangour Hospital, for the radiological studies, Mr G A Smith, of the Royal Victoria Hospital, Belfast for the illustrations, and the *Journal of Bone and Joint Surgery* for permission to reproduce the radiographs in figs 1–3

ig. 7—Repair of large compound hole in layers with local skin flaps. The shaded portions were turned in to provide lining.

importance of properly designed flaps and the fact that, since the scalp lacks elasticity, suturing under tension may lead to serious delay in healing. The surgeon's object should be to give safe cover by relieving tension at the point of danger, and free grafts should be reserved for areas of no importance. To achieve this the incision outlining a rotation flap must be generously planned, and the area of the flap must greatly exceed the area of the original defect. It is wise to remember that the scalp covers a convex surface, and the laws of spherical geometry involve unexpected difficulties in obtaining the necessary gain. It has been estimated that to advance the apex of a scalp rotation flap by 1 in. demands a curved incision 8 in. long; otherwise the secondary defect will not be self-closing.

A complex problem arises in relation to skin defects associated with loss of mucosa. Such compound defects are met in carcinoma or lupus of the face involving the nasal or the paranasal cavities, in full-thickness losses of lip or cheek, and in pharyngeal fistulæ following radical surgery for cancer of the larynx. In each case it is imperative to establish a lining that carries an adequate blood-supply, and that is therefore a living flap of either mucosa or inverted skin. On the face it is usual to turn in a flap of adjacent skin, which then lies inside out; this generally involves a turn of 180°, and special care is therefore necessary to prevent kinking of the "hinge" (fig. 7). These operations are commonly carried out as a secondary procedure, but in selected cases they should be completed as a primary repair. A similar problem is the closure of a large pharyngostome, which may be a troublesome operation for the laryngologist, especially if it is complicated by the effects of adjacent irradiation. Again two layers are usually essential, but the necessary skin cover can in most cases be given in a single operation, without recourse to many stages and multiple migrations.

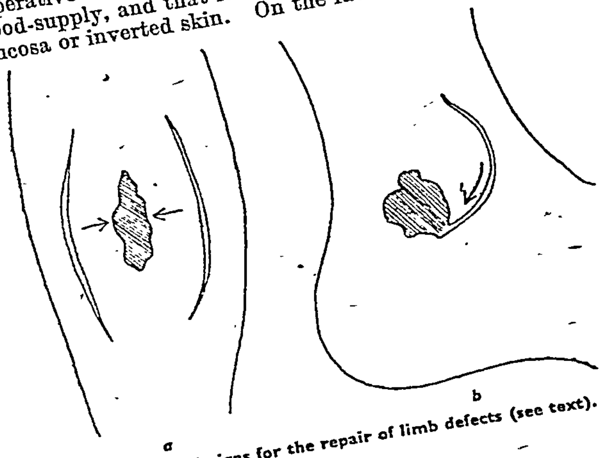

Fig. 8—Inferior designs for the repair of limb defects (see text).

A different principle lies behind the Abbe and Estlander flaps in lip repairs; these flaps include all layers—skin, muscle, and mucosa—and are nourished by a narrow *arterial* pedicle. The same principle is involved in the "fan" flap of Gillies. This also includes the full thickness of the cheek, and (unlike most other flaps) may be designed with a broad apex. It is based on a narrow pedicle near the corner of the mouth and is rotated to reconstitute the upper or the lower lip. The secondary defect should be self-closing.

INFERIOR DESIGNS

A final section must be devoted to those flaps of ill-conceived design which bring the methods under discussion into bad repute. Some of these useless designs are copied from textbook to textbook and thus survive, even in these enlightened days, to mislead the unwary. A summary in relation to figs. 8 and 9 should suffice:

(1) Relaxation incisions (except rarely on the scalp) are unsound and dangerous; this applies particularly to the limbs. The resultant sloughing, however, may still be seen as an occasional but needless complication of orthopædic repair (fig. 8*a*).

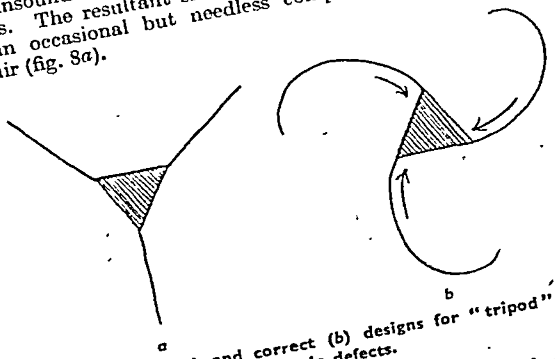

Fig. 9—Incorrect (*a*) and correct (*b*) designs for "tripod" closure of scalp defects.

(2) The Z-plasty, when misapplied to an elliptical defect, does not relieve lateral tension but only increases it.

(3) The inadequate "rotation" flap which is too short and too narrow is always a menace, especially near the ankle (fig. 8*b*).

(4) The *straight-legged* tripod incision for scalp defects is a futile procedure which is still figured in some modern textbooks. Harvey Cushing's three-flap operation succeeds admirably by virtue of the curve of its limbs (fig. 9).

SUMMARY

The repair of skin defects with local skin flaps as a primary operation has great advantages which are often overlooked.

A variety of designs are available, and there are wide indications for the use of these flaps, particularly for primary repair in operations for malignant disease.

The special problem of simultaneously providing lining and skin cover may often be solved by a single manœuvre

I am much indebted to my colleague Mr. R. H. Dale for h diagrams and to Mr. G. Clemetson for the photographs.

A.F., auricular fibrillation.
C.I., cardiac infarction.
H.H.F., hypertensive heart failure.

The bladder was emptied and the urine discarded. A glass of water (about 150–200 ml.) was given by mouth. 1 ml. of a sterile solution containing 6 mg. of P.S.P. was injected intramuscularly. At one hour and two hours urine was voided and saved. The output of P.S.P. in each specimen of urine was estimated separately. The estimations on the first half of the patients in each group were made by technicians at the London Hospital by visual colorimetry against a freshly prepared standard; the later ones were made by me with an Evans photo-electric colorimeter with an Ilford green no. 404 filter.

In the patients tested at the London Hospital the urea-concentration test was done simultaneously, 15 g. urea in 100 ml. water being given by mouth instead of the water alone. Cottet and Courjaret (1946) showed that urea did not affect the output of P.S.P., but they pointed out that oliguria and polyuria caused an error in the test. The volumes of urine in the present series were 60–180 ml. per hour, most of them being 100–140 ml. per hour.

RESULTS

Controls

The percentage excretion in two hours of the administered dose of P.S.P. in the controls is recorded in tables I and II. In all these the excretion exceeded half the dose given, with a mean excretion of 68% in those aged 15–40 and 62% in those aged 45–75.

Ageing caused a slight but significant reduction in the excretion of P.S.P. over two hours and must be taken into account when considering the subsequent groups. Sex made no difference to the amount of P.S.P. excreted.

TABLE V—EXCRETION OF P.S.P. BY PATIENTS WITH HEART-FAILURE AND WITH A PREVIOUSLY NORMAL BLOOD-PRESSURE

Case no.	Age (yr.)	Sex	P.S.P. % in 2 hr.	Blood-pressure (mm. Hg)		Diagnosis

A.F. auricular fibrillation.
A.S. aortic stenosis.
C.I. cardiac infarction.
A.I. aortic incompetence.
A.S.D. atrial septal defect.
M.S. mitral stenosis.
* The diagnosis was confirmed at necropsy, which showed no evidence of hypertension.

Hypertension Without Heart-failure

The percentage of P.S.P. excreted in this group is recorded in table III. In all except two patients it was less than 50% in two hours, with a mean value of 41.5%. All these patients were aged more than 45 except two who were aged 39 and 33.

Hypertension With Heart-failure

The percentage of P.S.P. excreted in two hours in this group is recorded in table IV. It was less than 45% in all but one of the patients, with a mean value of 34.3%. With only one exception the patients were aged more than 40.

Heart-failure Without Hypertension

The percentage of P.S.P. excreted in two hours is recorded in table V. It was greater than 45% with one exception; the mean value was 54%. All the patients were aged more than 45 except for one aged 24.

CONCLUSION

There is a clear difference between the amount of P.S.P. excreted by the controls and that excreted by the patients with uncomplicated essential hypertension, both in the mean and in the individual values. Similarly the amounts of P.S.P. excreted by the patients with heart-failure and hypertension were significantly lower than those excreted by the patients with heart-failure without antecedent hypertension. These findings are summarised in table VI and the accompanying figure.

TABLE VI—SUMMARY AND ANALYSIS OF RESULTS

Group	No. in group	Mean P.S.P. % in 2 hr.	Standard error of mean	
Controls 15–40 yr.	18	68	1.95	
Controls 45–75 yr.	15	62	1.78	$t = 8.9$, $p < 0.001$
Uncomplicated hypertension	25	41.5	1.43	
Hypertension with heart-failure	21	34.3	1.98	$t = 7.6$, $p < 0.001$
Heart-failure with no hypertension	16	54	1.65	

DISCUSSION

From these results it appears that the P.S.P. excretion test over two hours can be of definite assistance in diagnosing previous hypertension, whether or not heart-failure is present, provided the latter is not severe. For, although the excretion is decreased in heart-failure alone, there is a further significant reduction if hypertension is or has been present, and this can usually be detected by the test.

P.S.P. is eliminated both by glomerular filtration and by tubular excretion, and the latter is believed to be the more important (Goldring et al. 1936). However, when 6 mg. of P.S.P. is injected intramuscularly the plasma P.S.P. levels do not reach the range where self-depression of the tubular excretion of P.S.P. is important. Thus, at the plasma levels obtaining by this method of P.S.P. loading, the excretion of P.S.P. depends mainly on renal plasma flow. Heart-failure reduces renal plasma flow (Merrill 1946), and hypertension by itself also reduces it (Goldring and Chasis 1944). Moreover, where cardiac failure and hypertension coexist, each causes its own reduction in renal plasma flow; hence lower figures are obtained than when either condition exists alone (Brod and Fejfar 1950).

In this way the present results can be explained. Nevertheless it is difficult to reconcile them with those of other workers who have found normal values for the two-hour P.S.P.-excretion test except relatively late in the course of hypertensive disease (Goldring and Chasis 1944).

CLINICAL FINDINGS

All our patients, except cases 6 and 12, showed high glucose tolerance, 8 shallow insulin-tolerance curves (diminished insulin sensitivity), as is usual in pituitary overactivity, and 5 normal glucose tolerance. The basal metabolic rate (B.M.R.) and the specific dynamic action of protein showed no definite changes in any direction; nor was the serum-cholesterol level instructive. The serum-potassium and serum-sodium levels and the urinary excretion of 17-ketosteroids were not helpful in assessing the adrenal cortical function.

All our patients had, of course, high red-cell counts. A count of less than 6,000,000 per c.mm. was found only in case 2 (pituitary obese), case 3 (obese diabetic), and case 6 (erythræmic). The hæmatocrit values were also high—between 46·5 and 79. Six cases of erythræmia showed moderate leucocytosis (above 10,000 per c.mm. in cases 6, 9, 10, 12, 13, and 14); and the differential count in all the cases showed a slight shift to the left, as is usual in erythræmia. The blood volumes, determined by the dilution method with Evans blue, in all the cases examined (cases 2, 3, 4, 7, 8, 9, 11, 12, and 14) were increased owing to the enlargement of the red cells (Heilmeyer 1931). It was moderately increased (7·5–8·46 litres) in the patients with symptomatic pituitary polycythæmia (cases 2, 3, and 4), and greatly increased (12·7–17·0 litres) in the patients with erythræmia (cases 11, 8, 12, and 9). Heilmeyer gives similar values. There were only two patients with erythræmia (cases 7 and 14) who had blood volumes as low as 8·2 and 9 litres.

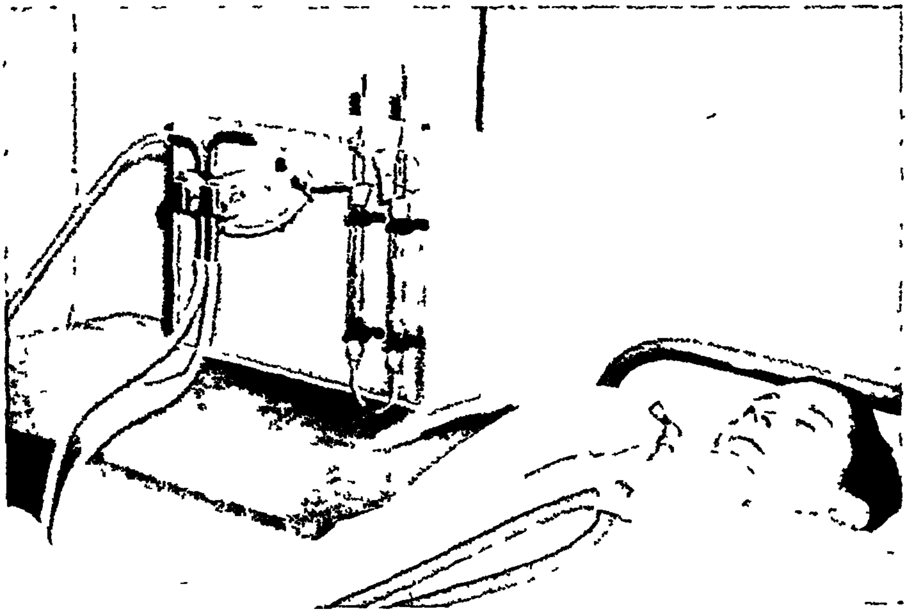

Fig 1—The respirator

the connection occurring, an electrical impulse is sent through the "booster" (O) to the corresponding coil on the valve, and the piston moves to the opposite side

Movement of the fluid from one tube to the other is through the connecting-tubes I and II By means of these connecting-tubes it is possible to vary the time-ratio between inspiration and expiration—a ratio that should be 1 2 During inhalation the fluid moves (fig 2) from L_1 to L_2, partly through I, where the flow is reduced by the screw-valve P, but mainly through II, where the flow is not checked A small light ball at the bottom of L_2 is lifted by the inflow through II and does not hinder it, so that it takes place quickly and easily During inhalation, II thus functions as a shunt, and the rising of the fluid in L_2 is not retarded in relation to the rise in pressure in the patient's air-passages

On the fall in pressure in L_1 that takes place during expiration, the flow of the fluid will be reversed, and the two floats move back to the position of equilibrium (fig 4), but the ball will now prevent a flow back through II, and allow passage only through I The rise of the fluid in L_1 can therefore be retarded in relation to the fall in pressure on the fluid by the use of the screw P, and the exhalation phase made as long as may be desirable

OPERATION OF THE RESPIRATOR

A coherent impression of the working of the apparatus is best obtained by following its operation through the three phases of inspiration, expiration and expiratory pause

Inspiration begins with the piston at the extreme left (fig 2) The rubber bag now distended, presses its contents through the valve, the inspiration tube, and the Y connection down into the lungs Here the pressure rises and this passes over through the side tube K to L_1, and presses the fluid over into L_2, while the little ball is raised by the inflow Inspiration is ended when the floater in L_2 closes the electric circuit between the electrodes there (fig 3) At the same moment the current flows through the right-hand coil and the piston moves over to the extreme right position

Now *expiration* begins (fig 4) The elasticity of the thorax presses the gas out through the valve to the outer air, and at the same time the pressure over the fluid in L_1 falls Because of the screw-valve P, the fluid flows slowly back through I from L_2 to L_1—so slowly that there is time for both complete expiration and the *physiological* expiratory pause This ends when the float comes back to its electrodes and closes the circuit between them (fig 5), which starts off the next inspiration

REGULATION OF THE RESPIRATOR

In artificial respiration such as this only three factors appear to need regulation (1) the rate of respiration, (2) the time-relation between inhalation and exhalation, and (3) the maximal pressure in the lungs at the end of the inhalation phase (inspiration pressure)

Rate of respiration—If the inspiration pressure is kept constant (by maintaining the position of the electrodes in L_2) the respiratory rate can be increased, in the first place, by shortening the inspiratory phase If the same pressure in the lungs is to be obtained in a shorter time, this must be done by filling the lungs in a shorter time Therefore the rate must be increased by increasing the flow from the oxygen cylinder If the time ratio between

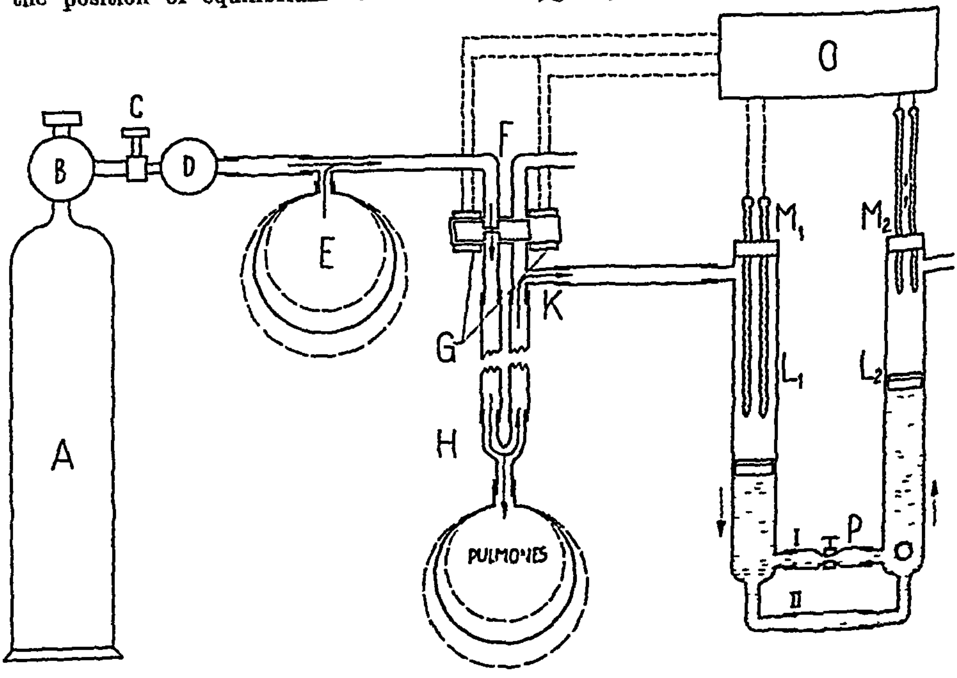

Fig 2—Diagram of respirator, during inspiration

clinical findings show, a considerable part in blood formation.

Though Flaks et al. (1937, 1938) and A. Querido and G. A. Overbeek (cited by Aschkenasy 1952) assume the existence of a specific pituitary erythropoietic hormone, and the latter workers also that of a specific hæmolytic one, their findings need confirmation; if they are right, *p*-hydroxypropiophenone might act on these hormones.

The hæmopoietic or hæmolytic action of the target glands of the pituitary seems not to be due to specific hormones, for there is no certain proof of their existence. For instance, Mansfeld's (1943) myelotropic hormone is hypothetical. Changes in the formation and destruction of the blood might be due to decreased activity of the target glands brought about through the depressant action of *p*-hydroxypropiophenone on the secretion of the pituitary hormones which act on those glands.

Our experiments show that the decrease of the red cells and of the hæmatocrit does not proceed pari passu, but that the decrease of the hæmatocrit lags behind that of the red cells at least in some cases, producing a tendency to hyperchromia and macrocytosis of the red cells. This suggests that *p*-hydroxypropiophenone affects primarily the formation of the red-cell stroma, perhaps through the inhibition of nucleoproteid synthesis, and only secondarily th[illegible] of action of *p*-hydroxypropiophenone, we think that our therapeutic results support our theory of the pathogenesis of symptomatic pituitary polycythæmia and erythræmia (Haynal and Gráf 1950) and refute Aschkenasy's (1952) objection based on the failure of our previous therapeutic experiments with sex hormones, thiamine, and radiotherapy.

The treatment of erythræmia and symptomatic pituitary polycythæmia with *p*-hydroxypropiophenone is aimed at the cause of these diseases as opposed to the alleviation of their symptoms, such as has been provided hitherto by the dietetic reduction of materials necessary for blood formation, the diminution of erythrocytes and the blood volume through venesection, hæmolysis with phenylhydrazine, and the inhibition of the erythropoietic action of the bone-marrow with arsenic, radiotherapy, benzene, or radioactive phosphorus.

SUMMARY

On the assumptions that (1) symptomatic polycythæmia and erythræmia are due to overactivity of the pituitary gland, and (2) *p*-hy[illegible] depresses the pituitary gland, four ca[illegible] and nine of erythræmia were treated with *p*-hydroxypropiophenone. Treatment in six of the cases of erythræmia was incomplete because the drug became unobtainable.

Undesirable effects were seen in two cases of incompletely treated erythræmia: nausea and vomiting in one, and toxicoderma in the other.

Therapeutic effects were observed on the red cells, hæmatocrit, and hæmoglobin, but were not permanent without a maintenance dosage. The results were obtained without hæmolysis and without histological signs of toxic effects on the bone-marrow.

It is claimed that these results support the theory that symptomatic polycythæmia and erythræmia are due to overactivity of the pituitary gland, and that treatment with *p*-hydroxypropiophenone aims at the cure of these diseases by the abolition of their cause—i.e., the overactivity of the pituitary—rather than the alleviation of their symptoms, such as has been provided by other remedies hitherto.

Grateful acknowledgment is made to the staff of our laboratory and especially to our clinical chemists Dr. Lily Pollák and Dr. Maria Stützel.

MECHANISM AND TREATMENT OF SPINAL-CORD DISORDERS ASSOCIATED WITH CERVICAL SPONDYLOSIS

A. R. TAYLOR
M.A., M.B. Aberd., F.R.C.S.E.
NEUROLOGICAL SURGEON, ROYAL VICTORIA HOSPITAL, BELFAST

DISORDERS of the spinal cord associated with cervical spondylosis have received intermittent attention since the beginning of this century. Bailey and Casamajor (1911) described five cases, and further contributions were made by Parker and Adson (1925), Krabbe (1928), Junghagen (1929), Beadle (1931), Mixter and Barr (1934), Morton (1936), and others.

In recent years there has been greater recognition of the clinical syndromes associated with spondylotic changes in the cervical spine, and Kahn (1947), Bucy et al. (1948), Spillane and Lloyd (1951, 1952), Allen (1952), Bedford et al. (1952), and Russell Brain et al. (1952) have reviewed the subject from the standpoints of pathology, ætiology, clinical presentation, and treatment. From these reviews there emerges a clear and complete clinical picture, but the way in which the lesions of the spinal cord are produced remains somewhat obscure. As a result opinions differ about the best line of treatment.

It remains to be satisfactorily explained how a syndrome commonly associated with compression of the spinal cord is produced without apparent naked-eye compression of the cord visible at operation or post mortem. Queckenstedt's test for obstruction of the subarachnoid pathways is usually negative, and the protein content of the cerebrospinal fluid (C.S.F.) is seldom increased to the amount of that commonly observed caudal to an obstruction.

In this paper an attempt is made to show that in cervical spondylosis the spinal cord is compressed not by the disc protrusions alone but also by the ligamenta flava, which move forward as the neck is extended. Treatment is considered in the light of this hypothesis. In the interests of simplicity "disc protrusion" is taken to signify either simple nuclear extrusion, which is relatively uncommon, or ligamentous and annular thickening, with secondary osteophyte formation, which together form the transverse bars found in about 80% of cases.

CLINICAL SYNDROMES

Cervical disc protrusions cause symptoms referable to the nerve-roots, to the spinal cord, or to both. The neuritic syndromes caused by root compression are familiar and will not be described here. Spinal-cord compression is manifest as spastic paraparesis, with or without involvement of one or both upper limbs, or as hemi-cord dysfunction—variants of the Brown-Séquard syndrome. The clinical variations were well described by Stookey (1928) associated with ecchondromata, which disc lesions were then thought to be. Further good descriptions have been given by Allen (1952), Spillane and Lloyd (1952), and Brain et al. (1952). These observers agree that the

The third patient, a 25 year old woman had no spontaneous respiration at all She has used the apparatus since Jan 20 She is pleased with it, and her clinical condition has been satisfactory

Blegdam Hospital, after an observation period, has ordered a further 12 respirators, to replace the students (still numerous) who supply manual respiration

POSSIBLE FURTHER USES OF THE RESPIRATOR

This apparatus has proved suitable for poliomyelitis patients, and can be adjusted to help patients who are either wholly incapable or can manage only a modicum of spontaneous respiration

It seems natural, however to consider also the possibility of using the apparatus in other cases where the patient's own respiration has stopped or is not functioning adequately Here one is in the sphere of hypothesis, since such other uses have not yet been tested

Poisoning

Cases of poisoning—particularly in patients who have taken morphine or other drugs with a gross depressive effect on the respiratory centre—are at present where spontaneous respiration is inadequate, treated by manual pressure ventilation after intubation—perhaps tracheotomy The use of the respirator in such cases might be considered

Accidents

Carbon-monoxide poisoning, drowning accidents, and similar conditions where artificial respiration is indicated seem, in theory at any rate, suitable for treatment with automatic pressure ventilation, applied through a closed mask

Operations

In thoracic operations where the pleura is opened and the negative Donders's pressure is removed, and oxygen and an anæsthetic are given by manual pressure ventilation after intubation, the use of the respirator seems possible The current that flows between the electrodes in the tube L_1 is so small that no electric spark is produced The danger of explosion in cases where the anæsthetic used is an explosive mixture is thus infinitesimal By a slight modification in the design, however, the apparatus may be made absolutely safe in this respect

Deep anæsthesia, alone or combined with curare injection to secure complete relaxation of the muscles, seems to provide a field where it is important to ensure respiration The capacity of the apparatus to "cooperate" with the patient would seem to be of value here The same may perhaps be true in the post anæsthetic phase

Deficient Oxygenation

Finally—to mention other and more remote possibilities—it may be possible, for short periods and by the use of a closed mask, to try the effect of such moderate pressure ventilation in cases where the oxygenation of the blood is insufficient because of superficial respiration This may arise in connection with reduction in efficient lung tissue—e g serious pneumonia lung œdema from uncompensated heart failure, shock traumatic and spontaneous pneumothorax

This, however, is only guessing which still has to be checked

SUMMARY

A new principle of automatic artificial respiration has been applied to the construction of a respirator, which has so far proved satisfactory in cases of poliomyelitis

This respirator, which is easily and cheaply made, operates in response to variations in pressure in the respiratory system, with which it has an airtight connection

The apparatus may also prove useful in the treatment of conditions other than poliomyelitis

THE BIOLOGICAL ACTIVITY OF TRIIODOTHYRONINE

E G Tomich
B Sc Lond F R I C

E A Woollett

From the Pharmacology Unit, Glaxo Laboratories, Greenford Middlesex

THE finding of Gross and Pitt-Rivers (1952) that 3 5 3'-L triiodothyronine was three or four times as active as L thyroxine in preventing goitre in thiouracil treated rats prompted us to repeat their experiment and to determine the relative potencies by two other methods

A comparison by the goitre prevention assay was performed in duplicate, 74 rats being used in the two experiments Groups of rats received daily subcutaneous injections of the two compounds at two dose levels for ten days and a control group was injected with saline solution alone Throughout the experiment all five groups were offered ad lib tap-water containing 0 1% thiouracil A sixth group, of uninjected rats, got plain tap water On the eleventh day the rats were killed and their thyroid glands were removed and weighed The combined results from the two experiments were statistically analysed and showed L-triiodothyronine to be 7 4 times as active as L thyroxine

A second comparison, by a mouse anoxia method (Smith et al 1947), was made in triplicate, each experiment involving eight groups of 9 mice each Three groups were treated with L thyroxine at different dose levels, and the remaining five groups received graded amounts of L triiodothyronine Subcutaneous injections were given on the first, third, and fifth days of the experiment On the seventh day individual survival times were measured The combined results of the three experiments gave an activity ratio of 4 5 1 in favour of L triiodothyronine

Finally the effects of the two compounds on the rate of consumption of oxygen were compared in rats by a modification of the technique of Maclagan and Sheahan (1950) In one experiment the materials were injected subcutaneously at three dose levels to six groups of 4 rats each Daily injections were given on seven consecutive days, and individual oxygen consumption rates were determined daily throughout the experiment L triiodothyronine was found to be 5 1 times as active as L thyroxine A similar experiment, in which the drugs were given by mouth, gave a ratio of 5 3

During the course of absorption and excretion studies in rats and cats with labelled L triiodothyronine it was found that recoveries measured by the Blau (1935) isolation technique were similar to those obtained with thyroxine This technique has been widely used in the past by workers interested in the metabolism of thyroxine If exogenous thyroxine is deiodinated to triiodothyronine in the body, those who have used the Blau method for recovering thyroxine from animal tissues may well have been estimating triiodothyronine alone or a mixture of both substances

produced evidence (not present in flexion) of obstruction of C.S.F. In one of the cases reported by Bucy et al. (1948) myelography showed obstruction of the oil column at the C5–C6 interspace only when the neck was hyperextended. Spillane and Lloyd (1952) observed that at the site of disc protrusion obstruction occurred in most cases only during hyperextension. This position was used routinely in [illegible] patients. Brain et al. (1952) noted greater deformity of the oil column in the extended position of the neck. Kaplan and Foster Kennedy (1950) drew attention to obstruction of the C.S.F., judged by Queckenstedt's test, in the extended position of the neck in eight patients who had either cervical disc protrusion or cervical arachnoiditis. A control series of more than 200 patients without such lesions showed no obstruction to the C.S.F. in any position of the neck.

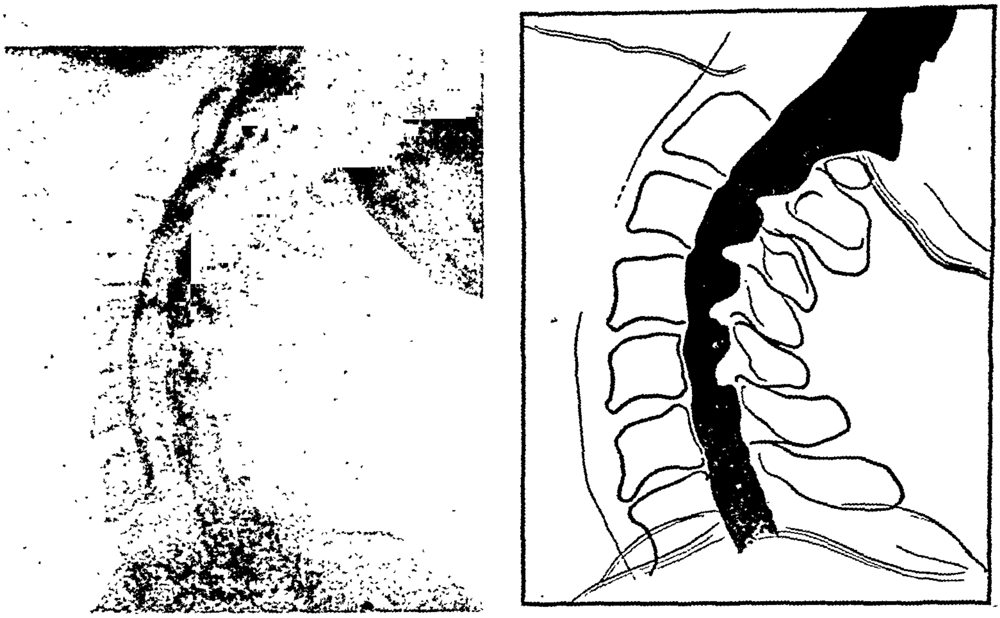

Fig. 3—Myelogram of cervical spine in cadaver showing compression between disc protrusions between C5 and C6 and between C6 and C7 and ligamenta flava bulging forward in hyperextension.

It is therefore suggested that the ligamenta flava, compressed and bulging intraspinally as the neck is extended, act as an intermittent compressing agent capable of producing gradual changes in the vasculature of the spinal cord, the precise nature of which is uncertain. The cord is held in position to receive each impact of recurring compression by the spondylitic elevation in front of it.

TREATMENT

If the evidence for the compressing rôle of the ligamenta flava is held to be adequate, a rational line of treatment can be planned accordingly.

[illegible] took place in patients treated [illegible] et al. (1952) and by Spillane and Lloyd (1951). Immobilisation limits extension and prevents recurring trauma from the ligamenta flava. It cannot create any more room for the embarrassed spinal cord, because there is no inflammation to subside with rest. To be effective, immobilisation must continue for life. Whenever movement is restored, intermittent compression recurs with each movement of extension.

Reviews of Books

Frontal Lobotomy and Affective Behaviour

A Neurophysiological Analysis JOHN F FULTON, M D, Sterling professor of physiology, Yale University London Chapman & Hall 1951 Pp 159 21*s*

Professor Fulton has an outstanding claim to write on this subject—or rather speak on it, for these were the Salmon lectures of 1950—for it was observations made by him and Carlyle Jacobsen on chimpanzees that led Egas Moniz to try interrupting the frontal projections in man as a method of treating mental disorder He writes with masterly selection and control of his material After reviewing the historical background, he considers the advances lately made in relating structure to function in the cerebral cortex and its connections, and some recent studies of behaviour in primates after section of various pathways The final division of the book is concerned with the effect upon mental disorders of more limited procedures than radical leucotomy Dr Fulton believes that the radical operation should now be abandoned, because of the intellectual impairment which follows from any lesion of the lateral surface of the frontal lobe or section of its projections on this the evidence is perhaps less conclusive than he believes

Management of Abdominal Operations

Editor RODNEY MAINGOT, F R C S London H K Lewis 1953 Pp 1253 £6

Mr Maingot expresses the hope that the title of this large book adequately explains its scope but the reader—and indeed some of the 33 contributors—may think it errs on the side of conservatism

Much of the book is concerned with physiological factors which have a bearing on abdominal operations—such as water and electrolyte balance, thrombosis, acidæmia and alkalæmia—and the parts played by vitamins, antibiotics, and so on Then there is a full consideration of anæsthesia, of chest complications, of thrombosis, and of early ambulation In this part of the book a great amount of knowledge has been collected, and it is all up to date though there seems to be no account of water intoxication, nor mention of proctoclysis But a judicial summing-up and an assessment of the value of many procedures recommended would really have been of more use than the encyclopædic methods used by most contributors in the section on anæsthesia for gastrectomy, for instance, the author carefully conceals his predilection, if he has one, for any particular method

The second part deals with regional abdominal disease Some of these chapters—those on the biliary tract, the œsophagus and gastric surgery in general—are excellent, and the discussion on vagotomy is helpful and illuminating, but some chapters suffer from the inability of the writers to make up their minds Thus some describe operative procedures while others do not Detailed technique from an experienced operator would have been welcomed, for example, in the account of herniorrhaphy—still an unsolved problem The simple steps of an interval appendicectomy are described, but no guidance is given on how to avoid injury to the nerves of the bladder in the excision of a carcinoma of the rectum Suction drainage is advised after all major abdominal operations on the gastro-intestinal tract, indeed, surgeons just now seem obsessed with suction drainage For intestinal obstruction it is recommended in all cases except those of strangulation But what indubitable signs of strangulation are there? We are not told There is an extraordinary recommendation to stretch the sphincter ani (to paralyse it) after operations in acute appendicitis for the avoidance of gaseous distension But why not pass a rectal tube, should the need arise? Why tear the fibres of the sphincter ani?

The third part consists of two chapters only—an elementary account of aseptic surgery and a very useful dictionary of clinical pathological values in health and disease

The editor admits repetition, dogmatism overlapping, lack of balance, different opinions, and lack of style, and he makes out a good case for the freedom of the contributor But a little less licence would have made the book more readable and comprehensible

Metabolic Interrelations

With Special Reference to Calcium Transactions of the 4th Macy Conference Editor E C REIFENSTEIN, M D, director, Oklahoma Medical Research Institute New York Josiah Macy, Jr, Foundation 1952 Pp 262 $4 60

AT the conference reported here 27 participants discussed 20 papers, dealing with different aspects of bone structure and formation The reporting is of the literal type common to this large series, so that closely argued theses, obviously destined for separate publication, are interspersed with the unbuttoned trivia of peripheral experts

The first five papers deal with the collagenous matrix of bone and cartilage, then comes a group of papers dealing with calcification and the crystal structure of calcium salts, sodium, fluoride, and sulphur in bone are each discussed in one paper Perhaps the two contributions of most general interest are the introductory paper by R H Follis on the structure, formation, and distribution of calcium and bone matrix, and J Gross's account of the in vitro fibrogenesis of collagen, beautifully illustrated by electron photomicrographs The final paper in the series has the inviting title, "Composition of teeth in relation to caries susceptibility", but it is a one page account of a small series of animal experiments and there was no discussion

This volume can be recommended to anyone interested in a fundamental approach to the structure and mineralisation of bone matrix, collagenologists should welcome the first five papers, and the paper on the turnover of bone sodium doubles previous estimates of the amount of sodium in this metabolically inaccessible situation

Practical Dermatology

GEORGE M LEWIS, M D, F A C P, professor of clinical medicine (dermatology), Cornell University Medical College Philadelphia and London W B Saunders 1952 Pp 328 37*s* 6*d*

THIS is designed as a text for medical students, a practical guide for general practitioners, and an aid in orientation for other specialists Professor Lewis confines himself to a description of the clinical features and management of the more common skin disorders, and has purposely omitted histology, mycology, bacteriology, and other subjects only indirectly related to dermatology The book is profusely illustrated in monochrome with 90 pages of photographs of uniformly good quality These are displayed in groups, with relevant textual details placed, as often as possible on the opposite page The chapter on animal infestations is particularly good, and supported by a veritable picture gallery—including everything from the commonplace if rarely photographed ova of *Pediculus vestimenti*, to the more rarely seen facies of the patient with trichiniasis Few of the author's opinions are controversial, but surely it is surprising to see seborrhoeic keratoses classified among the premalignant and malignant tumours Psychological factors are given adequate consideration and Professor Lewis rightly stresses that sympathetic history taking is often an important part of treatment He gives a short but useful bibliography of general texts and special monographs The chapter on dermatological formulæ is not of great value to doctors practising in the British Isles, since many of the proprietary preparations mentioned are not available in this country

The author has carried out very well what he set out to do

Anatomy of the Nervous System (9th ed Philadelphia and London W B Saunders 1953 Pp 581 42*s* 6*d*)—Dr S L Clark's latest revision of Ranson's well known textbook follows the pattern of the last edition Our knowledge of the structure and function of nervous pathways is growing so rapidly, under the stimulus of modern methods of study, that no textbook can include all that is known or surmised about them at its moment of publication, and Dr Clark is modestly aware of this Nevertheless, he has done his best, by adding new material and illustrations and by blending the account of structure with that of function, to grapple with his expanding subject

THE RENAL EXCRETION OF PHENOLSULPHONPHTHALEIN AS AN AID TO THE DIAGNOSIS OF PREVIOUS HYPERTENSION

J. VALLANCE-OWEN
M.A., M.D. Camb, M.R.C.P.

MEDICAL TUTOR AND SENIOR REGISTRAR, POSTGRADUATE MEDICAL SCHOOL OF LONDON

From the Cardiac Department, London Hospital, and the Department of Medicine, Postgraduate Medical School of London.

THIS investigation arose from the difficulty of diagnosing hypertension in older patients when the blood-pressure had fallen for any reason, notably following cardiac infarction. In such cases the signs of heart-failure often overshadow those of hypertension; and, although radiology will show considerable enlargement of the heart, such enlargement could be the outcome of cardiac infarction with or without failure. Again, the evidence of ventricular preponderance in the electrocardiogram may mask the changes of cardiac infarction, and a past history or record of hypertension is available in only a few cases. The changes in the retinal vessels, although of great value, are not always easily recognisable. The need for additional evidence of previous hypertension in these circumstances has been apparent for some time; for, although the treatment, usually that of heart-failure, is unaffected by this lack of information, the ultimate prognosis depends largely on an accurate diagnosis of the underlying ætiology.

TABLE I—EXCRETION OF P.S.P. BY YOUNG CONTROLS

Case no.	Age (yr.)	Sex	P.S.P. % in 2 hr.	Blood-pressure (mm. Hg)	Diagnosis
1	35	F	75	120/70	Fibroids
2	38	M	74	130/80	Healthy
3	16	F	70	130/70	Healthy
4	39	M	78	125/85	Healthy
5	34	F	56	105/65	Healthy
6	23	F	56	120/70	Enuresis
7	30	F	73	140/80	Pregnancy
8	29	M	61	120/80	Duodenal ulcer
9	31	F	75	115/80	Diabetes mellitus
10	27	F	75	130/80	Healthy
11	25	M	77	110/70	Healthy
12	27	F	58	115/75	Healthy
13	17	M	54	145/80	Healthy
14	23	F	62	130/80	Recent acute pyelitis
15	38	M	64	110/70	Pneumonia
16	28	F	80	130/80	Migraine
17	39	M	64	140/70	Gastric ulcer
18	34	M	70	150/80	Healthy

Further, some patients present with heart-failure and cardiac enlargement but without clinical or electrocardiographic manifestations of infarction, signs of a valvular lesion, or increase in the blood-pressure. The cause of the failure in this group is often difficult to determine and all too frequently ascribed to past hypertension, often on extremely slender grounds. In studying the results of routine renal efficiency tests made in the clinical laboratory of the London Hospital on patients with essential hypertension, an appreciable decrease below normal of phenolsulphonphthalein (P.S.P.) excretion in two hours was often noticed, although the urea-concentration test, blood-urea level, and catheter specimens of urine were almost invariably normal.

TABLE II—EXCRETION OF P.S.P. BY OLDER CONTROLS

Case no.	Age (yr.)	Sex	P.S.P. % in 2 hr.	Blood-pressure (mm. Hg)	Diagnosis

MATERIAL

The present investigation was made to determine the value of the P.S.P.-excretion test as an indication of antecedent hypertension; for this purpose tests were made in four groups of patients:

(1) *Controls.*—This group comprised thirty-three persons: eighteen aged 15–40 and fifteen aged 45–75. All were either considered healthy or were ambulant patients with no disease referable to the renal tract or to the cardiovascular system, and none had hypertension.

(2) *Hypertension without heart-failure.*—This group was made up of twenty-five patients with essential hypertension having no evidence of heart-failure and no significant albuminuria. The retinal arterioles showed irregularity and narrowing of their lumen, and in some cases there were also scattered flame-shaped hæmorrhages. Patients with papillœdema were excluded from the series.

(3) *Hypertension with heart-failure.*—In this group there were twenty-one patients in whom heart-failure complicated essential hypertension. None had valvular heart-disease. Several of the patients had normal blood-pressures on admission, although previously they were known to be hypertensive.

(4) *Heart-failure without hypertension.*—Sixteen patients with heart-failure from rheumatic heart-disease, cor pulmonale, or cardiac infarction, but with a normal blood-pressure, made up this group. In allocating patients to this group care was taken to establish the fact that, before the onset of cardiac failure, the blood-pressure had been within normal limits. This was most readily told by reference to previous case-notes in most cases; and, when these were not available, by study of the retinal, electrocardiographic, and cardioscopic findings. Even then the cases were accepted only if these tests provided unequivocal evidence.

TABLE III—EXCRETION OF P.S.P. BY PATIENTS WITH HYPERTENSION WITHOUT HEART-FAILURE

Case no.	Age (yr.)	Sex	P.S.P. % in 2 hr.	Blood-pressure (mm. Hg)

52	65	M	50	180/110
53	59	M	38	230/140
54	66	M	39	210/110
55	50	F	47	260/140
56	70	M	42	170/120(b) 130/80(now)
57	39	F	37	185/110
58	33	F	45	200/115

(a) = 18 mos. ago. (b) = 5 mos. ago.

The signs of heart-failure in the last two groups included a raised jugular venous pressure, an enlarged tender liver, and œdema of the feet. In no patient could the failure be called severe.

METHOD

The P.S.P. test of Rowntree and Geraghty (1910) was made on the patients, and the procedure was as follows:

air results in the most severe and most long-continued headache This immediate headache, which usually lasts about forty-eight hours, is attributed by VON STORCH et al[10] to the irritant effect of the air It may be followed by the low-tension headache, and total replacement seems again most likely to produce this second headache Most therapeutic agents now introduced into the theca have been tested thoroughly in advance The early sulphonamides, and the early forms of penicillin, carried their own special risks, now happily eliminated, but care should be taken in the use of any new drug Streptomycin has a definite irritant effect on the meninges and causes an alteration in the constitution of the C S F which persists for some weeks

If drugs or other agents are to be introduced into the theca they should be known to be harmless There is much sense in KENNEDY's[9] plea that spinal anæsthesia should be used only when general anæsthesia is absolutely contra-indicated Pneumo-encephalography can be performed humanely and efficiently with the introduction of 30–40 c cm of air, provided that this is combined with painstaking positioning of the patient in order to display all the ventricular system It seems unnaturally savage to insist on complete replacement in order to obtain complete ventricular visualisation with only two or three films, at the expense of twelve hours of acute agony for the patient and a severe enough headache lasting several days With regard to the actual technique of puncture, is it too banal to suggest that the operator should approach this with the care and precision which he would like to have exercised on himself? Strict asepsis, and careful insertion of a sharp, small-bore needle into the correct space, with the minimum of trauma to intrathecal and extrathecal tissues, will avoid all the hazards in groups one and two, and will, in addition, do much to reduce the risk of headache HART[11] reports favourably on the use of a pencil-point needle The occurrence of headaches in 40% of ambulant patients in SCIARRA's[7] series confirms the idea that twenty-four hours' rest in bed is advisable after lumbar puncture Elevation of the feet perhaps has little to commend it, but there seems to be some point in increasing the fluid intake

Despite all care, however, the typical headache will develop in some cases The time honoured technique of keeping the patient in bed and horizontal, since it is the most comfortable position, should immediately be adopted, and the return to the vertical made gradually over the next few days CROSBY[12] suggests the use of β-pyridyl carbinol tartrate ('Roniacol Tartrate') for the long-term headache after pneumo-encephalography, and this substance may possibly alleviate the low-tension headache from lumbar puncture and spinal anæsthesia PFEFFER[13] records good results from treating post-lumbar-puncture headache with deoxycortone acetate by mouth He gives this, in a polyethylene glycol wax base, in doses of 2 mg six-hourly for one to four days Some workers recommend raising the C S F pressure by a second puncture and introduction of saline intrathecally Patients tend to resist this idea, and indeed the second lumbar puncture may result in further ill effects DEUTSCH[14] speaks well of the administration of 5% ethyl alcohol in 5% glucose for the treatment of post-lumbar puncture headache, he attributes the beneficial effects of the alcohol to dilatation of the choroid plexuses and increased formation of C S F These new remedies need to be further assessed, but meanwhile the clinician should aim, by perfecting his technique, to prevent the state of affairs that calls for such measures

Epidemiology of Accidents

IN 1950, 13,363 people in England and Wales were killed by accident Such was the compelling figure behind the recent discussion on the epidemiology of accidents by the epidemiology and preventive medicine section of the Royal Society of Medicine The section's mission is partly apostolic in propagating the use of epidemiological method in non-infectious disease, and partly educational in emphasising the urgency of the medical and social problem of death by violence In the section's discussion, on March 20, Dr W P D LOGAN, chief medical statistician to the General Register Office, said that violence had now supplanted infectious disease as the major cause of death in childhood, in 1950 about a third of all the deaths among schoolboys and young men were due to accidents, and the age distribution of accident mortality was marked by another rise among people of both sexes over the age of 65 Dissection of the tables of the Registrar-General's vital statistical report is the inevitable preliminary in social pathology, and the usual epidemiological concepts of host, agent and environment form a useful framework for the synthesis of ideas on this subject

Mr WILLIAM GISSANE, director of the Birmingham Accident Hospital, pointed out that agent virulence may be affected by coincidental changes in habits and environment, the danger of gas and electric fires is enhanced by the contemporary fashion of crinoline dresses made of inflammable fibre mixtures Host variation in susceptibility and exposure is reflected in many facets of the statistical tables The distribution of deaths in road accidents reveals the risk to the young and the inexperienced as pedestrians, cyclists, and motor-cyclists But experience is not all, in 1950 eight of the pedal-cyclists killed were over 80 years of age, and since the number of octogenarian cyclists seriously exposed to risk on the highway is small, the hazard to them must be great Women, on the other hand, are particularly prone to death by burning in the home both in early life and in old age There are sex differences in the nature of injuries, even in deaths due to falls In men 31% of the deaths from falls in 1950 were due to fractures of the skull and 38% to fractures of a limb, whereas among women the corresponding proportions were 8 and 74% The frequency of fracture of the femur among elderly women may be accounted for by the type of shoe worn and the bone fragility among the very old, who are more often women The male predilection for fracturing the skull is less easily explained, particularly as the adverse sex ratio is present throughout working life and even in childhood, indeed six times as many boys as girls are killed by falling objects fracturing

Percentage excretion of P.S.P. in 2 hours in four groups of patients. Horizontal bar indicates mean for each group.

SUMMARY

The excretion of P.S.P. after two hours in patients with hypertension was significantly lower than in healthy subjects.

It was also lower in patients with hypertensive heart-failure than in patients with heart-failure from other causes, irrespective of the state of the blood-pressure at the time.

Excretion of less than 50% in the absence of heart-failure, or 45% if heart-failure is present, strongly supports the diagnosis of hypertension.

This test helps to establish the diagnosis of hypertension in cases where the blood-pressure value for any reason, especially because of cardiac infarction, is natural at the time.

I wish to thank Dr. William Evans for his encouragement and criticism, and the physicians at Hammersmith Hospital for access to patients under their care.

A NEW RESPIRATOR

CLAUS BANG

ASSISTANT PHYSICIAN, COUNTY HOSPITAL, SKIVE, DENMARK

IN the autumn of 1952 we had in Denmark a poliomyelitis epidemic of the utmost severity, as regards both the type of illness and the numbers affected. There was a high proportion of cases with bulbar involvement, and the treatment of patients with respiratory paralysis proved a difficult problem.

At Blegdam Hospital, Copenhagen, where treatment was largely centralised, it soon became necessary to supplement the ordinary methods of applying artificial respiration to these patients. In coöperation with the anæsthetists, good results were obtained by positive-pressure ventilation (Lassen 1953). The method is briefly as follows:

> A high tracheotomy is performed, and a rubber tube with an inflatable cuff is fitted closely into the patient's trachea. The lungs are then insufflated by manual compression of a rubber bag filled with oxygen or a mixture of oxygen and nitrogen. The gas circulates in a closed system; exhaled gas passes through an absorber, which removes the carbon dioxide, and back to the rubber bag. The oxygen consumed is replaced from an oxygen cylinder.

Manual ventilation was performed by medical students of Copenhagen University. They worked 8-hour shifts, so the treatment of each patient needed three students every 24 hours. This method was adopted elsewhere in Denmark, including the medical department of the County Hospital, Skive. Its use here, however, was more difficult, since no students are available, and manual respiration had therefore to be carried out by the nurses. Replacement of human labour by some automatic method was thus highly desirable.

A respirator constructed here has proved an effective alternative (fig. 1). It is simple to make, and, compared with other respirators, it is very cheap. The essence of its function is that it depends on variation in pressure *in the patient's respiratory system, with which the* apparatus has an airtight connection. The highest pressure in the lungs at the close of the inspiratory phase sets off expiration. Not till the pressure in the lungs equals atmospheric pressure can the next inspiration start. There is thus a constant action and reaction between patient and respirator.

CONSTRUCTION OF THE RESPIRATOR

The respirator is shown diagrammatically in fig. 2.

The energy necessary to insufflate the patient's lungs is delivered by a cylinder of compressed gas (A), fitted with a manometer (B), a tap (C) for regulating the flow, and a flow-meter (D) by which the flow can be measured in litres per minute. The flow amounts to 7–10 litres a minute. Pure oxygen may be used, or a mixture of oxygen and nitrogen, or, in suitable cases, compressed air. On its way from cylinder to patient the gas is humidified by passage through water. With poliomyelitis patients an airtight connection is established through a high tracheotomy opening.

In a rubber bag (E) which acts as a reservoir container, the flow from the cylinder collects while the patient is exhaling into the outer air. During the subsequent inhalation the rubber bag, now distended, presses some of its contents into the patient's lungs under moderate pressure (130–190 mm. water).

Both inspired and expired gas pass through a single valve (F). In the valve-chamber is a piston which fits closely to the inside of the chamber except in the middle, where there is space for the gas to pass through the chamber. The piston is actuated by the magnetic fields produced by two coils (G). When the piston is at the extreme left position (fig. 2), allowing the gas to pass from the rubber bag to the patient, the valve is closed for connection to the outside air. Conversely, the piston at the extreme right position (fig. 4) allows exhalation while cutting off the flow from the rubber bladder, which therefore fills during this phase.

From the valve two tubes lead to the patient, with a Y-connection (H) just above the patient's trachea. On the valve is yet another tube (K) through which the pressure obtaining in the patient's lungs is transferred to the tube L_1.

L_1 and L_2 are two connected tubes; L_1 is in airtight connection with the patient's air-passages, while L_2 is open to the outer air. These tubes contain a fluid of very low volatility and of viscosity equal to that of water. When this fluid touches the electrodes M_1 and M_2 it makes an electrical connection between them. In figs. 3 and 5 this is shown as taking place through two floats on the surface of the fluid.

The electrodes marked M_1 are set so that they are connected by the float in L_1 when the two columns of fluid are standing at the same height—i.e., when they are in equilibrium (fig. 5). The height of the electrodes M_2 is variable. This pair of electrodes is connected when a certain pressure in tube L_1 has sent the float in L_2 up to the electrodes (fig. 3). This pressure, which is equal to that in the lungs, is therefore controlled by the height of the electrodes above the position of equilibrium. On so far reached in these social experiments will create a demand for further and more sustained, efforts to improve their techniques

If the social scientist has sometimes been less successful than we, and he, had hoped, is it not perhaps because we are not clear what we can reasonably expect him to offer? He comes to us from a background of academic freedom where he has always enjoyed the right of free and lively discussion, and one of the most important things he can teach is respect for facts and tolerance for other cultures In the long run, said Professor **Myrdal**, irrationality cannot stand up to facts, and the social scientist who can persuade us to give up social superstitions and admit that our prejudices, though cherished, are probably ill founded, has made the world a safer and pleasanter place to live in (The local need for tuition in the technique of rational discussion is made equally clear by any newspaper correspondence, parliamentary discussion, or conversation in a bus on a controversial subject, such as capital punishment, the death penalty, education, or racial segregation) Again, though we offer the social scientist opportunities for collecting facts and amassing data which are closed to the academic worker, are we sufficiently jealous of his integrity? As Professor **Myrdal** pointed out, "science is criticism, and social sciences imply criticism of society" Will the State, he asked, continue to grant the social scientist the freedom he needs and enjoys? He must be at liberty to state the truth even when it is inopportune, and he must not be allowed to grow shy of broader issues

These are ways in which we can help the social scientist But some of his difficulties are technical and beyond our aid His fellow scientists, indeed, have always been somewhat suspicious of the purity of his methods They have an uneasy and not unjustified feeling that he is at least as interested in what *should be* as in what *is* And it is true that the social scientist (like the doctor) stands in more intimate relation to his material than most scientists, for he is a participant observer of actual social processes He is willy nilly a part of the process he is observing and of the national cultures against whose values the facts must be assessed This brought Professor **Myrdal** to the social scientist's greatest handicap The more closely facts are associated with people, the more difficult they are to present objectively hence the social scientist would be hard put to it to produce a collection of facts untinged by judgment, and indeed they would probably be valueless if he did There are no answers without questions and by the selection of his questions the social scientist shows his interest But this difficulty Professor **Myrdal** maintained must be faced not evaded Valued premises must be explicit and deliberately chosen, not implicit and concealed Furthermore there are, he averred, in most situations several sets of perhaps conflicting valuations It is small wonder then that the sociologist with his present inefficient tools is sometimes at a loss to offer firm prognoses and plans in the face of these imponderables Yet he has certainly moved a long way from the days when the politicians were content to listen politely to his advice Today he already shares in administration and legislation tomorrow he may well find that he is holding the restless baby called international tensions

Annotations

COSTS AND VALUES

Just before the House of Commons adjourned last week the Minister of Health announced the formation of a new committee to review the cost of the National Health Service The terms of this announcement were such as to disturb not only members of the Opposition but also a good many people who are working in one way or another to make the service a success The committee's terms of reference (see p 749), with their emphasis on control of Exchequer funds, on the burdens on the Exchequer, and on the avoidance of a rising charge, and their remark about "the maintenance of an adequate service" sounded as though they were framed by some one who regarded the N H S as primarily a liability, which must now be reduced they suggested that this was a Treasury committee appointed to propose or justify cuts Fortunately Mr Macleod's replies to his questioners were reassuring in at least one important particular—the absence of haste Cuts which are made hastily are too often made blindly, and at the tender age of 5 the National Health Service really must be spared any further slapdash surgery The Minister, however, made it plain that the committee will not be pressed for time, and we may hope therefore that it will be able to study the implications of any changes it may recommend We cannot yet tell whether it will be well qualified to form "value judgments" on, for example, the proportion of the national income which the service can properly claim, or the distribution of funds between the different parts, but it should certainly be in a position to display the close association between finance and policy, and to discuss both incentives to economy and disincentives such as excessive central control Though ad hoc committees are not an ideal substitute for a consistent policy, few will deny the very real need for dispassionate inquiry into the matters which Mr Guillebaud and his colleagues will have to consider

MAINTENANCE TREATMENT IN PERNICIOUS ANÆMIA

Not long ago we noted that vitamin B_{12} (cyanocobalamin) was being increasingly used for the treatment of pernicious anæmia[1] Further reports have confirmed the value of this substance in maintaining a proper level of red cells and hæmoglobin Murphy and Howard[2] treated 8 patients with 1 μg of crystalline vitamin B_{12} daily, given intramuscularly, for 21–39 months They found that this treatment gave effective control and maintained the blood counts at satisfactory levels One of their patients already had locomotor difficulties caused by involvement of the central nervous system this disability was neither aggravated nor improved Murphy and Howard suggest that 1 3 μg of crystalline B_{12} is equivalent to 1 *U S P* "anti anæmic unit" of liver extract Meacham and Heinle[3] carried out a more elaborate survey They had previously shown that a vitamin B_{12} concentrate given intramuscularly once every 3–4 weeks in doses equivalent to 1 μg per day did not suffice for proper maintenance[4] They took 21 patients and increased the dose to 3 μg daily, before the increase 14 had red cell counts of less than 4 million per c mm, after 11–16 months' treatment all 21 had counts of a higher level The "concentrate" they were using has proved to be a mixture of vitamin B_{12} (cyanocobalamin) and vitamin B_{12b} (hydroxocobalamin) So far inspiration and expiration is to be kept at 1 : 2, then expiration must likewise be shortened by easing the screw of the valve P. A reduction of the rate is obtained, conversely, by reducing the flow, which causes inspiration to take place more slowly. By tightening the screw at P, expiration can be kept at the correct ratio to inspiration.

The *time-relation between inspiration and expiration* is regulated as described above, by means of the screw at P.

Maximal pressure in the lungs at the end of inspiration is controlled by the height of the electrodes in L_2, and may thus be varied from patient to patient, and according to the needs of each individual from time to time. It is possible, for example, for the space of a couple of inhalations, to raise the electrodes a little above the normal, and so, as prophylaxis against atelectasis, to give the patient a couple of higher-pressure " sighs."

CLINICAL EXPERIENCE

Two respirators, constructed on the principles already described, have been used since the middle of January, 1953, in the medical department of the County Hospital, Skive, on two boys with poliomyelitis.

The first, 13 years of age, is completely quadriplegic and up to the time of writing (end of February) has been quite incapable of spontaneous respiration. The second, 8 years of age, has had extensive paralysis in all four extremities but power of movement in certain groups of muscles is greatly improving. This patient, after a fortnight of total paralysis of the respiratory system, has for the last three weeks shown signs of a return of respiratory movement—at first in the form of contractions of the auxiliary respiratory muscles. Later, the diaphragm and the intercostal musculature began to work, but only for short periods and to a very limited extent, quite inadequate for effective ventilation of the lungs.

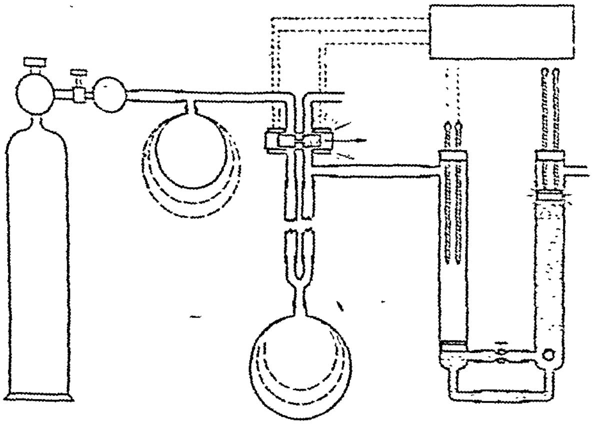

Fig. 3—Diagram of respirator, at the start of expiration.

High tracheotomy was performed on both these patients on arrival; and respiration was given manually, since at that time the construction of the new respirators was not finished. When these were fitted, the condition of both boys—in their own judgment and in ours—visibly improved. It should be remembered that manual respiration had had to be undertaken by our nurses, who in this matter were quite without experience. Immediately after the change both boys fell asleep, colour and pulse improved, while their blood-pressure steadied at a lower and more satisfactory level.

It would seem that with this respirator it is possible to give some training in spontaneous respiration when this shows signs of returning. In the case of the 8-year-old boy, who has begun to make spontaneous respiratory movements, we are gradually lowering the inspiratory pressure, and at the same time training him to work in step with the respirator. The result of this close collaboration between patient and respirator will be that an increasingly effective spontaneous breathing eventually gives the patient the upper hand so that the respirator will come to work in step with him. A later example will show this.

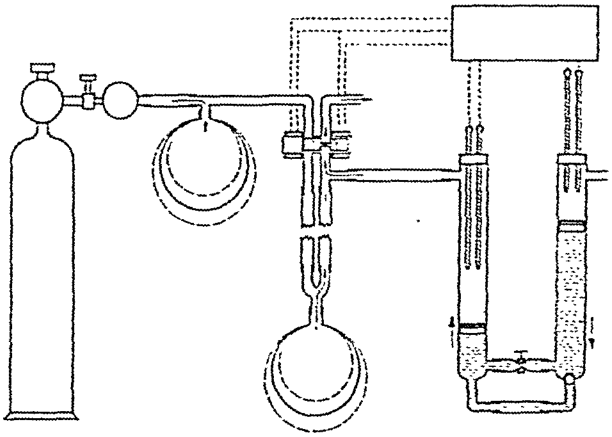

Fig. 4—Diagram of respirator, during expiration.

On Jan. 20, 1953, a third respirator was demonstrated at the Blegdam Hospital, Copenhagen, on three patients with paralysis of the respiratory system.

The first, a man about 30 years of age, with no spontaneous respiration, was satisfied with the apparatus and found it better than the " student " method.

The second, also a man, had at the time of the demonstration so much spontaneous respiration that he could manage without help for 18–20 hours out of the 24. His unaided respiration was quick and superficial, with a rate of about 40 per min. When the respirator was first fitted to this patient, it was set with a quite high inspiration pressure and a rate of about 20 per min. The patient's own weak respiratory movements seemed to have little or no influence on the variations in the pressure in the lungs thus obtained, but the difference between the slow pace of the apparatus and the patient's own respiratory movements seemed unpleasant to him. The inspiration pressure was therefore reduced and the rate increased, so that the respirator worked in time with the patient's spontaneous respiratory movements. Then, as the patient put it, it was he that breathed in, but the respirator helped him.

The accompanying figures show how the respirator can support a spontaneous effort at respiration. Such an effort will draw air into the lungs. This suction will transfer itself to the tube L_1, where consequently the float will connect the electrodes, and the respirator will momentarily support the patient's own superficial inhalation with a fuller, higher-pressure inhalation.

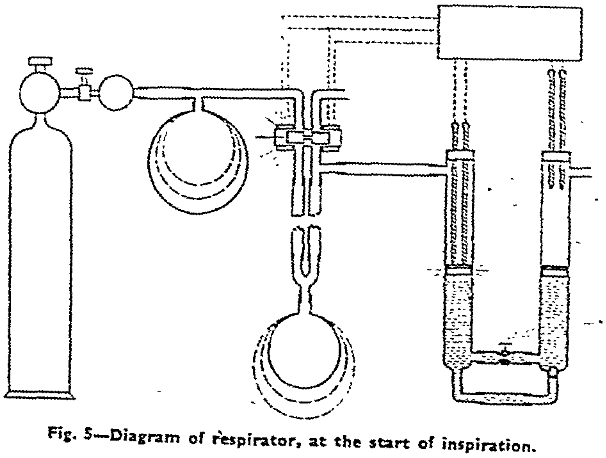

Fig. 5—Diagram of respirator, at the start of inspiration.

measuring the tensile strength of wounds In control rabbits, week-old wounds had twice the tensile strength of wounds from cortisone treated animals Administration of ascorbic acid with cortisone did not materially affect this result, nor did it influence the histological appearance of depressed fibroplasia In scorbutic guineapigs cortisone treatment, though it seemed to ameliorate the scurvy, did not further impair the tensile strength of wounds

Thus although both scurvy and administration of cortisone lead to defective collagen formation, the relationship between ascorbic acid and cortisone cannot be simply defined As Bourne points out, the failure of development of collagen fibres from these two mechanisms cannot be attributed to their action at the same level Cortisone has many known effects on connective tissue—cells, fibres, and ground substance—but at present these effects cannot be linked with the biological action of vitamin C

CONFERENCE ON ENDEMIC GOITRE

ALMOST every country has areas of endemic goitre This was therefore a particularly appropriate subject for debate at a conference of experts arranged by W H O and held last December at the National Institute for Medical Research, London The findings of this conference have now been reviewed by J B Stanbury[1]

On the theoretical side endemic goitre presents no problems the thyroid needs iodine to make its hormone, if insufficient iodine is present in the diet the thyroid enlarges and forms a goitre The normal daily output of thyroid hormone contains about 0 2 mg of iodine Much of this iodine, however, is re-used after breakdown of the hormone, so the actual minimum iodine requirements of the body are of the order of 0 1 mg per day If all persons living in iodine deficient areas were provided with an extra ration of 0 1 mg of iodine daily, there should be no goitre

This theoretical expectation is largely borne out in practice, and in several areas—notably Switzerland and Michigan—the incidence of endemic goitre has been strikingly reduced by the provision of iodised salt It would be too much to hope that this simple expedient will entirely eliminate goitre, since it is by no means uncommon in areas where iodine is abundant Nor does extra iodine have much effect on established goitre, even in deficient areas, its usefulness lies in prevention rather than cure But a great deal would be achieved by applying in every area of endemic goitre the prophylactic measures successfully used in Switzerland and Michigan This aim has so far been thwarted by various factors—political, economic, and chemical Legislatures are—rightly—wary of compulsory contamination of foodstuffs In backward countries the supply of salt is often not refined, hence iodine would have to be added by hand, at a prohibitive cost Finally, iodide proves unstable and unwilling to remain uniformly mixed with salt under very hot or very damp conditions A proposal before the conference was that, instead of iodide, iodate should be used, since this is much more stable Studies with labelled iodate have shown that its iodine is available to the thyroid, while its toxicity appears to be very low This may prove to be the most useful form in which to distribute iodine in tropical countries

These practical difficulties have caused some people to wonder whether iodine prophylaxis is worth the effort and expense Most goitres are quite harmless Although there is some evidence in endemic areas of an increased incidence of thyrotoxicosis and (more doubtfully) of thyroid cancer, the disadvantages of having a goitre are more often æsthetic than medical, and would not justify any great effort at prophylaxis The strongest argument for a determined effort to eradicate endemic goitre comes from the load of endemic cretinism which so often accompanies it The case would be greatly strengthened if it were proved that the feeblemindedness, deaf-mutism, retardation of growth, and economic unproductiveness which are often found in endemic goitre areas are also causally related to iodine deficiency So far such claims have not been properly substantiated If they were, the argument for insisting on iodine prophylaxis, despite all practical difficulties, would be overwhelming

TRACING THE STAPHYLOCOCCUS

THE investigation of staphylococcal infections has been greatly aided by the development of new methods, including the coagulase test, the typing of strains by serological and bacteriophage techniques, and the recognition of penicillin-resistant strains Phage typing of *Staphylococcus aureus* differs from Vi phage typing of typhoid bacilli in that it depends, not on the more or less specific lysis of a strain by one of the phages in critical test dilution, but on the pattern of lysis produced by the series of typing phages Precise typing is of special value in tracing the sources and paths of cross-infection, and Hood[1] has described a way of facilitating large numbers of tests for the purposes of a burns research unit

The essence of this method is the preliminary testing of strains with a small number of pools of phages, each of which rarely cross reacts with the other pools and contains single phages usually forming associated patterns of lysis Staphylococci can adsorb the phages in the pool to which they are resistant, but they still give the same pattern of lysis with those in the pool to which they are sensitive as they do with single phages The reliability of the method was confirmed in an extensive trial It was also found that the phages of serological group A, whether single or pooled, were stable at their test dilution for at least a month at 0°–5°C, but that those of group B were usually stable for only 2–3 weeks The method adopted by Hood as a routine is to test new strains first against five phage pools, each containing 5–10 single phages, the results are read after 18 hours at 30°C or 6 hours at 37°C They are then tested against the single phages in any pool giving a positive result, the broth culture of staphylococci used for inoculating the plates for the preliminary test can be used again for this purpose

The prevalence and spread of *Staph aureus* in the noses of infants and mothers not in hospital has been studied by Ludlam[2] in five child-welfare clinics In the first 2 months of life the organism was more often present in infants who had been born in hospital than in infants born at home, in the last half of the first year the same difference was observed The prevalence fell steadily with age from its early high levels of about 70–86% in the hospital-born infants and 60% in the home born infants to a level much below that of the normal adult population In the mothers of these infants the prevalence (40–60%) was higher than the adult normal level only in the first 2 months after delivery, at that time the prevalence in those delivered in hospital was also higher than in those delivered at home In contradistinction to previous observations made in maternity hospitals there was an association between nasal carriage of staphylococci in infants and in mothers, but only during the first few months Penicillin resistant staphylococci were much commoner in infants up to 5 months of age and their mothers who had been delivered in one hospital than in another hospital or at home but swabs taken after this was known showed a high proportion of resistant strains from the nurses and infants and the dust of the nurseries at both hospitals The investigation yielded many phage types Of 35 instances

Preliminary Communication

THE RENAL DUCTS OF BELLINI

OBSERVATIONS IN NEWBORN BABIES

In examining routine sections of kidneys of adults or of children one very rarely sees what appears to be a communication between the pelvis and the openings of the ducts of Bellini in the renal papillæ. One always has the impression that the histological section has missed the place where the duct opens into the pelvis.

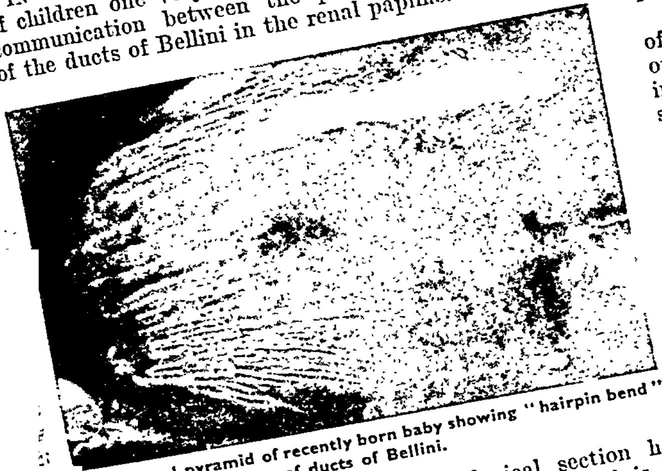

Fig. 1—Renal pyramid of recently born baby showing "hairpin bend" of ducts of Bellini.

Experimentally it has been possible to inject the whole circulatory system, both arterial and venous, of the kidney, but no-one has succeeded in injecting its secretory system. Two facts are very striking about the physio-anatomy of the collecting tubes:

1. If, when making retrograde pyelograms, the operator exerts pressure to fill the whole pelvis, instead of injecting the ducts of Bellini, as is to be expected, he injects the pelvic veins—the phenomenon of pyelovenous back flow (Hinman and Lee-Brown 1924).

2. Aseptic renal calculi are formed at the tips of the papillæ as though there were a barrier between the renal pelvis and the secretory system of the kidney (Randall 1940, Scheele 1951).

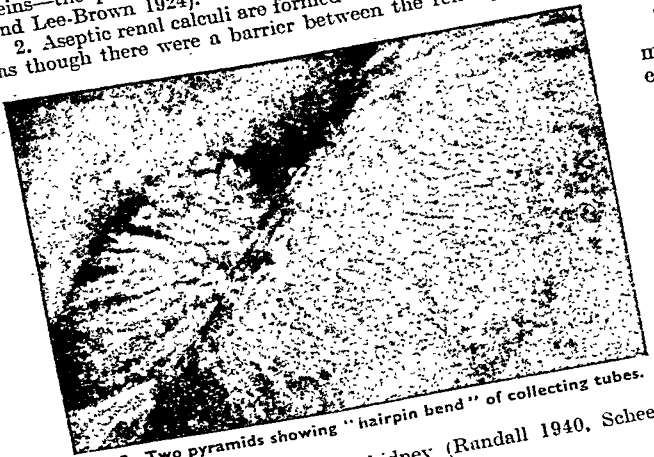

Fig. 2—Two pyramids showing "hairpin bend" of collecting tubes.

Physiologically we can study the excretory system of the kidney by examining those of babies recently born at term. In some of these cases it can be seen that the whole of the pyramids of the kidneys contain a "uric-acid precipitate" which fills the terminal collecting tubes (figs. 1 and 2), and by studying these kidneys under the low power we can see that the ducts of Bellini do not end in the renal pelvis. They seem to join another duct of Bellini and to finish in what appears to be a "hairpin bend." If the kidney is examined when very fresh, we see what looks like epithelium with some small vessels covering the tip of the papillæ. By sectioning these kidneys we can observe how the uric acid fills the terminal ducts, but these do not appear to be in actual contact with the renal pelvis (fig. 3).

Encouraged by this observation, I am now studying different kidneys to ascertain (1) if this absence of openings of the ducts of Bellini is to be seen only in babies recently born at term; (2) if this absence is peculiar to some papillæ and not to the whole of the renal pyramids; and (3) if at a later age the ducts of Bellini develop openings and drain the urine directly into the renal pelvis.

After having examined a few hundred routine sections of kidneys of all ages, and some serial sections of this organ from different animals, especially the cat (because in this animal the kidney has only one pyramid) I am sceptical of accepting the existence of openings of the ducts of Bellini, and I am considering the possibility that in the normal kidney the urine is dialysed through a pelvic epithelium and not excreted by the ducts of Bellini into the renal pelvis.

I am now studying this anatomical detail by serial sectioning of different kidneys and by taking a photomicrograph film of the sections to show, objectively, the existence or not of openings of the ducts of Bellini.

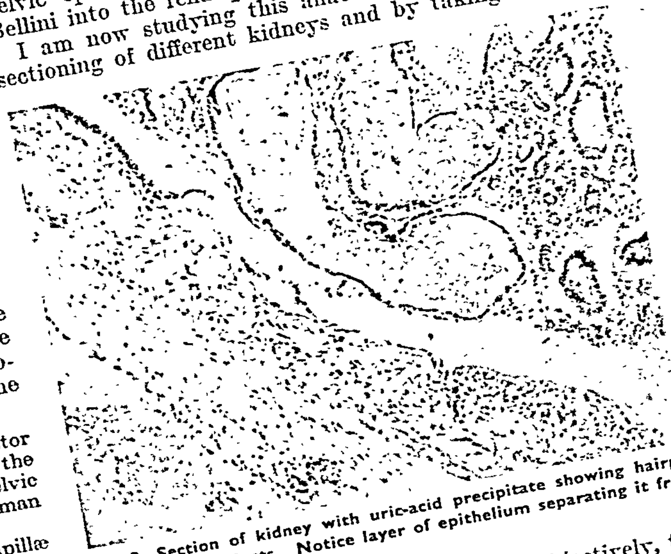

Fig. 3—Section of kidney with uric-acid precipitate showing hairpin tip of Bellini ducts. Notice layer of epithelium separating it from renal pelvis.

Thanks are due to the medical staff of Booth Hall Hospital and the Duchess of York Hospital for Babies for the use of their material, and to Mr. T. Walsh, A.I.M.L.T., and Miss A. J. Orrell for the histological preparations. The Endowment Fund of Booth Hall Hospital gave a grant towards the expenses of this research.

"The method of scientific publication in this country is notoriously somewhat peculiar. Although much research is entirely paid for from public funds, little money is available from this source for the publication of the results, and without publication such work is usually abortive. Publication of the results of research work is largely undertaken by what are, in effect, coöperatives of the research workers themselves and the spare-time labours of unpaid editors and officials. Scientific societies are able to make claims on the Government grant in aid of scientific publications (which is administered by the Royal Society), but this fund is proving inadequate. The long-term solution is the rationalisation of the publication of research. In the meantime there is need for the grant in aid of scientific publications to be increased and for a similar fund to be made available to students of the humanities."

From the Departments of Preventive Medicine and Medicine, School of Medicine, Western Reserve University, Cleveland, Ohio and the Streptococcal Disease Laboratory, Warren Air Force Base, Wyoming

IN the past fifteen years knowledge of the behaviour of streptococcal infections has increased greatly, thanks primarily to the work of Griffith,[1] Lancefield, and their co-workers[2] on the serological grouping and typing of streptococci It is now known, for example, that group-A β hæmolytic streptococci are the important group in human infections More than forty type strains have been identified in this group By serological techniques it is now possible to study the many factors related to the spread of these organisms in a population and to confirm the association of group-A streptococci with the non-suppurative complications—rheumatic fever and acute hæmorrhagic glomerulonephritis

General Aspects of Epidemiology of Human Streptococcal Infections

Much has been written about the epidemiology of β hæmolytic streptococcal infections in man Our intention here is to summarise some current concepts and to point out some deficiencies in knowledge

SOURCE OF INFECTING AGENT

Man is the only known natural reservoir of group A streptococci These organisms may occasionally be found in certain animals and in dust food and other substances In the latter circumstances, however the presence of streptococci may almost always be traced to human contamination and cannot be attributed to a biological requirement for survival of the organisms The ultimate source of streptococcal infections is thus the human reservoir

With few exceptions the habitat of the streptococcus in man is the upper respiratory tract One may ask, "What is known about the residence of the organisms at this site?" Perhaps the best answer is obtained by reviewing the sequence of events when a person acquires a new type of streptococcus

There is some evidence[3] that the organisms are first found in the anterior nares, which are presumably the site of deposition most readily available If the local factors are favourable at this site, a state of "parasitism" develops The streptococci multiply and spread with the result that large numbers are found in the nose, the throat, and probably the accessory sinuses In such circumstances clinical illness usually occurs but, as the acute symptoms subside, the number of streptococci in the nose rapidly decreases, and after two or three weeks few persons harbour the organisms in the anterior nares Likewise the number of streptococci in the throat decreases, but here the organism may persist for months[3,4]

An example of such persistence of the organism in the throat is found in the study of 53 "convalescent carriers" who acquired their streptococcal infections at the Francis E Warren Air Force Base in Wyoming[4] All were in the convalescent phase of untreated acute tonsillitis and pharyngitis due to group A streptococci At the end of three months' observation 90% of these men still harboured the infecting type of streptococcus in their throats

As the result, presumably, of acquisition of, and parasitism by, the group A streptococcus, type specific immune bodies appear in the serum within three to eight weeks, according to the type of streptococcus[5] Such antibodies are believed to be protective against the subsequent development of infection with the same type of organism[6]

During the period of parasitism, which here is considered to include the "convalescent carrier" state, a loss of type specificity may occur, presumably owing to a decrease in, or disappearance of, the M substance, or type specific protein, elaborated by the organism[4] That this may be so is shown by the fact that the production of M protein by carrier strains may be restored to apparently full capacity by animal passage[4,7]

This then, is the possible sequence of events when a person acquires a new type of group-A streptococcus Many questions, however, remain to be answered particularly regarding the significance of the observation thus far made For example, how long does the organism remain infectious in terms of spread in man (a qualitative attribute)? Or, what role does the numerical decrease in numbers play in the ability of the organism to spread (a quantitative attribute)? The answers to these two questions are not clear today The loss of M protein may mean a loss of virulence or a loss of the capacity to spread, or both Hamburger et al[8] have shown that the nasal carrier, excreting large numbers of organisms may induce spread of infection But all nasal carriers do not induce spread of infection or cause secondary cases[3] The only fact that seems clear is that "spread" indicated by secondary cases decreases as time elapses from the point of initial parasitism, regardless of whether the organism is harboured in the nose or in the throat[3,9]

MECHANISM OF SPREAD

The usual concept regarding spread of streptococci involves two general routes of transfer of organisms from the initial carrier to the recipient (1) directly between the two persons through physical contact or by droplets passing through the air for short distances, and (2) indirectly through fomites or via the air by means of droplet nuclei and dust[10] This classical theory of spread is considered to apply also to the agents causing other types of respiratory diseases

In fact, however, there is little if any direct evidence indicating the relative importance of these various modes of spread or even whether any of them is epidemiologi

THE LANCET

LONDON: SATURDAY, APRIL 11, 1953

Hazards of Lumbar Puncture

LUMBAR punctures, like crimes, are seldom committed in the contemplation of failure. If the operator reflects on his state of mind as he presses the needle into the theca, he is not likely to perceive in the foreground of his consciousness any clear image of the hazards attending the next few millimetres of forward progress. As he gains experience, his appreciation of the possible complications becomes keener; but, paradoxically, lumbar punctures are usually left to the most junior members of the hospital medical team.

The hazards of lumbar puncture fall into certain definite groups. In the first of these groups are the numerous effects of direct trauma from inexpert introduction of an unsatisfactory instrument. Ligaments, vessels, nerve-roots, spinal cord, and even the intervertebral discs have all suffered damage in this way; DRIPPS and VANDAM[1] have seen gelatinous material drip from a needle which had entered a nucleus pulposus. The second group comprises the infections that may follow septic technique or the injudicious introduction of the needle through an infected area of subdermal or deeper tissue. How often infection occurs one cannot know, since it attracts little publicity. It may result in either generalised meningitis or else an epidural abscess. There is the large third group of hazards, associated with disturbance of the dynamics of the cerebrospinal fluid (C.S.F.). The danger of herniation of the brain through tentorium or foramen magnum from puncture in the presence of increased intracranial pressure is well known, but not everyone is so familiar with the sudden exacerbation of symptoms and signs of a spinal-cord tumour from this procedure.[2] Such a mishap calls for fairly rapid surgical intervention since without relief of the increased pressure on the cord vessels irreversible changes may take place in the neurones. Furthermore, SCHUBE and RASKIN[3] point out that the withdrawal of as little as 10 ml. of fluid may result in sufficient vascular dilatation to induce intracerebral or meningeal hæmorrhage from diseased structures such as aneurysms or sclerotic vessels. Ocular palsy, usually an external rectus affection, is another possible sequel of lumbar puncture, and may be due to alteration in dynamics leading to stretching of the abducens nerve at some point in its long course. HUGHSON[4] has shown that pressures in the C.S.F. and in the auditory labyrinth are closely related; and the impairment of hearing that occasionally follows lumbar puncture, particularly in the presence of severe headache, may be due to lowering of C.S.F. pressure.

These dramatic incidents are not very common; but it is in this third group, of dynamic disturbance, that there falls the common problem of the post-lumbar-puncture headache. There is always doubt as to the nature of this headache. On the one hand the patient who is unaware of the possibility of it is less likely than others to become a victim; and on the other hand the doctor is naturally reluctant to ascribe head pains to his own efforts. This headache is precipitated or aggravated by the assumption of the erect posture; and it may be relieved by abdominal compression. It may come on as long as seven days after puncture; and, if untreated, it may continue for weeks. WOLFF,[5] among others,[1] believes that this headache results from the loss of C.S.F. and subsequent traction, displacement, or swelling of those parts of the cranial contents most susceptible to pain—the venous sinuses, the dura and its arteries, and the basal arteries. MARSHALL[6] has adduced evidence which seems to show that reduced C.S.F. pressure is not absolutely related to the headache; but most workers hold that relative lowering of the pressure, by initial withdrawal of samples and subsequent slow leakage from the puncture-hole, is the real cause. SCIARRA and CARTER[7] showed that headache is almost as common after simple puncture of the theca without withdrawal of C.S.F. as after withdrawal of 10–12 ml. of fluid: this point is corroborated by many reports that the use of small-bore needles greatly reduces the risk of headache. Occasionally, in addition to headache there may be vertigo, vomiting, and other symptoms of intracranial hypotension, including disturbed consciousness.[8]

These are the dangers of the simple diagnostic tap. If in addition anæsthetic, diagnostic, or therapeutic compounds are introduced into the theca a fresh chain of events is set up and new hazards arise. These constitute the fourth group. It may sometimes be difficult to decide whether symptoms following spinal anæsthesia are due to the lumbar puncture or to an unusual reaction to the anæsthetic. Most such headaches are of the leakage type already described, but occasionally there is a response that can be interpreted only in terms of meningeal irritation. Sphincter disturbance and even paralysis of the limbs may follow spinal anæsthesia.[9] Myelography, requiring the introduction of radio-opaque material into the theca via the cisternal or the lumbar route, invariably produces both headache and backache. Subsequent examination of the C.S.F. almost always reveals an increase in cells and protein, and it seems probable that almost all agents at present in use for myelography provoke some meningeal reaction. Pneumo-encephalography has complications of its own. The first few cubic centimetres of gas to reach the brain produces an immediate crashing headache which builds up as the volume of the gas in the subarachnoid space increases; maximum replacement of the C.S.F. with

of streptococcal infection with rheumatic fever Nephritis has been reported to occur after upper respiratory infections and infection with organisms such as the pneumococcus [24, 25] Moreover nephritis has only rarely followed epidemics of streptococcal infection, in contrast to rheumatic fever Examples of this are seen in a food-borne outbreak of type 5 streptococcus infection at Fort Bragg,[21] in which there were 3 instances of rheumatic fever among 100 cases of streptococcal infection, but no instances of acute nephritis Similarly, at Francis E Warren Air Force Base there were 1206 persons infected with typable group A streptococci, of whom 32 developed rheumatic fever but only 1 had nephritis [26]

Annual variations have been noted in the occurrence of nephritis At the Cleveland City Hospital,[27] for example, the number of admissions for acute nephritis varied from 29 to 85 in 1922–31 (see table) In 1921, however, there were 105 admissions, the year previously only 58 It is well known that hospital admissions reflect the influence of many factors, but the degree of variation here suggests the possibility of an identifiable factor

ADMISSIONS FOR ACUTE NEPHRITIS AT THE CLEVELAND CITY HOSPITAL *

Year	Number	Year	Number
1920	58	1926	41

1922	34	1928	29
1923	37	1929	29
1924	40	1930	38
1925	85	1931	38

* From Seegal et al [27]

Any epidemiological association of acute nephritis with hæmolytic streptococci must take into account such apparent discrepancies as these On reviewing the data obtained from 16 sporadic cases of nephritis in Cleveland and elsewhere [28] it was noted that type 12 streptococci were definitely or presumably the cause of the preceding infection in 14 instances, and type-4 streptococci in 2 instances One of the cases of nephritis, which developed after a type-12 streptococcal infection, was observed at Warren Air Force Base, where type-12 infections had been few, accounting for only 42 of the 1206 cases In Cleveland, where most of the sporadic cases were found, the results of weekly cultures were available over a three year period from a population of about 260 persons During this period type-12 streptococci had accounted for about 20% of the acquisitions of group A streptococci in the population Presumably, therefore, about 80% of the streptococcal infections in this area were caused by serological types other than 12, and yet nephritis was associated with the type-12 infections

The question therefore arose "Is acute nephritis associated only with a specific type or possibly with certain strains of a few types of streptococci, and can its occurrence be explained on this basis?" Several outbreaks or small epidemics of nephritis have been observed [28] In four of those in which the strains were typed,[26] type-12 streptococci were found in the patients or as the predominant streptococcus in the population in which the cases occurred

Recently in a recruit-training camp there has been an outbreak of streptococcal infections during which more than 100 cases of nephritis were observed [28] The type 12 streptococcus was the predominant organism in this outbreak A high attack-rate of nephritis followed the type 12 infections but not infections caused by other types Moreover some rheumatic fever also followed the type 12 illnesses

It therefore seems that the epidemiology of acute hæmorrhagic nephritis is basically the epidemiology of certain strains of group-A streptococci that are nephritogenic Studies are now in progress to define further this relationship

Summary

The epidemiology of the group-A hæmolytic streptococcal infections appears to account for the epidemiological behaviour of both rheumatic fever and acute hæmorrhagic glomerulonephritis

Rheumatic fever is not apparently associated with infection by any particular type of group A β hæmolytic streptococcus Nephritis, on the other hand, may follow infection only by certain types, here called nephritogenic

Further knowledge of group-A streptococcal infections should contribute greatly to our understanding of the behaviour of their non-suppurative complications

Typing and grouping sera were obtained through the New York State Department of Health, the Army Medical School, and the Communicable Disease Center, U S P.H S

"Government only works at all satisfactorily when you can go and talk to the man who is personally responsible for the decision that has been taken Remove this opportunity of personal contact and government becomes diffused and abstract We become numbers, black marks on white paper We fall into the diagnoses of the International Statistical Code, with a social group attached The person responsible becomes a 'they,' whose behaviour can never be observed directly, but can only be inferred 'They' are always polite, imperturbable 'They' attach great store to precedent 'They' do not grow old and resign age does not seem to weary them In this way individual human responsibility is being slowly lost Have we not the courage to restore it and allow the boards in touch with hospitals to take more of their own decisions?"—*Dr W I Card, Spectator*, March 20, 1953, p 336 their skulls. It does not need two people to generate a road accident; of about a thousand motor-cyclists (including passengers) who were killed on the road in 1950, 178 were killed by falling off their cycles, by running off the road, or in some way other than by a collision.

This raises the question of host susceptibility which, under the name of "accident-proneness," has excited the interest of many epidemiologists and psychologists since the report by GREENWOOD and WOODS appeared in 1919.[1] Studies by ADELSTEIN [2] on accidents among shunters in the South African railways has rekindled this interest, for he criticises the rather slipshod thinking that has distorted the original precision of the pioneers in this field. Accident-proneness—defined as an innate and immutable characteristic of the individual whereby some in a group sharing the same environmental risks have an unduly high share of the accidents—has been largely discounted as a major source of accident causation. If 50% of accidents are sustained by 40% of the workers, this does not mean that there exists an accident-prone minority, since if accidents were distributed at random among the group the distribution might be similar. The demonstration of individual excessive accident liability is fraught with difficulties, since it requires the continued observation of apparently similar people working long in the same environment. Such conditions are seldom found, particularly as the truly accident-prone may change his job after having had an accident. In flying, for example, the potentially accident-prone's first accident is liable to be his last, and there is no further opportunity for demonstrating that "repeating" which is the hall-mark of the condition. Despite the difficulties of isolating and defining accident-proneness, some clinicians are inclined to believe that temperamental qualities affect liability to error and accident. Sometimes this inference is soundly based on the objective tests designed to measure skill of performance under harassing circumstances.[3] Other workers venture into theories about the unconscious death wish as a cause of accidents. Commenting on this ADELSTEIN points out that the fatal-accident rate was much higher among shunters than among clerks; but there was no compensating rise in the number of suicides among the clerks.

However intriguing such theories of host variability may be, they should not blind us to the importance of environmental conditions. Crowding, for example, may be an important feature of what GORDON [4] has called "the reservoirs of infection" in accidents—the home and the highway. The frequency of reported accidents in factories with different degrees of congestion certainly suggests that overcrowding may have some bearing on the problem; but here again it is difficult to be sure that we are not measuring frequency of reporting rather than frequency of accident. Curiously enough, the rural roads seem to be more dangerous than those in the city, at least for males; and the same trend has been noted in the U.S.A.[4] Anyone who has served in a R.A.F. flying-station will remember the prevalent belief that accidents always happen in threes. Are accidents infectious? No-one seems to know; but new simple and sensitive tests [5] for detecting changes in the distribution of accidents in time and in space may throw clearer light on the relation of accidents to a changing environment.

GISSANE remarked at the meeting that the total loss inflicted on the community through death or injury by violence brooks no delay. We need, he said, special hospitals for treatment and reablement. But, as he also suggested, we need as part of the team field epidemiologists, based on the hospital, who can relate injury to circumstance, reveal the foci of special risk, and plan the measures of prevention.

The Social Scientist

OUR national way of meeting a crisis is to draw together; and the almost continuous crisis we have faced during the last forty years has led us more and more to club our resources and entrust to the State their fair distribution. But we should hardly have accepted the consequent interference with our private lives if we had not already been inclined to accept a modification of our society. This changing climate of opinion is largely traceable to the influence of the social scientist, and speakers at the first annual conference of the British Sociological Association, held in London at the end of last month,[6] showed a lively sense of their responsibilities.

In his opening address Prof. GUNNAR MYRDAL, who admitted to being himself an escaped economist, went back to the early sheltered days of social science, when its adherents were limited to a few university dons and a "restricted amateur fringe." This small group, he pointed out, brought forward big ideas: if the views of MALTHUS on population began as an academic abstraction, they certainly ended by affecting social policy. For a very long time, however, the social scientist's influence was ideological and he did not begin to emerge from his seclusion until the first world war, when the economist was summoned to help the politician and the Civil Servant. To begin with he was encouraged only to advise his more worldly colleagues in planning the new industrial controls made necessary by war; but he remained to share in administration. Nor after the war did he withdraw to his academic retreat; indeed he extended his work and called some of his fellow social scientists, such as the psychologists, to his side. Large business concerns were beginning to recognise, as Professor MYRDAL put it, "that their contacts with the public went beyond buying and selling," and they, too, now turned to the social scientist for help. The depression of the '20s, when facts about nutrition, health, and unemployment were urgently called for, gave the social scientist further opportunities, and the late war completed his emancipation. Such war-time devices as evacuation, rationing, and propaganda were largely dependent on his help, and in the years of so-called peace the anthropologist and the educator have taken an increasingly active part in such work as the democratisation of Japan, the occupation of Germany, and Colonial administration. Professor MYRDAL would not claim that they have been entirely successful with these unfamiliar tasks, but he believes that the results

over a number of years of H C TROWELL, who was unfortunately not able to attend the conference in person In a paper on the clinical aspects and treatment of kwashiorkor Trowell stressed that the disease develops in children fed a diet low in protein but relatively high in carbohydrate, this distinguishes it from general malnutrition, in which calorie deficiency predominates (In parenthesis, it may be remarked that though the theory of relative carbohydrate excess has been widely held, as is shown by names such as "sugar baby" and "starchy food dystrophy" applied to conditions of this type, and although it is in keeping with theoretical expectations based on the experimental work of Best and of Griffith, it has never received direct proof by measurements of actual dietary intake The difficulties of this are obvious, there is clearly an urgent need to surmount them) Trowell described how in kwashiorkor the main damage is inflicted on the organs with the highest protein turnover—not only liver, but also pancreas and gut Workers at Kampala have shown that in the pancreas both structural and functional lesions occur at an early stage In the subsequent discussion it became apparent that here is one point where studies in man seem to be in advance of those in the laboratory Although a reduction in enzyme content of pancreatic juice has been brought about in dogs and in rats by dietary means, there has so far been little success in producing experimentally the structural changes—atrophy and fine fibrosis—found in kwashiorkor The acute necrosis produced by the antimetabolite ethionine is not a characteristic lesion of that disease

Although Trowell underlined the importance of protein deficiency, he could not, in the present state of knowledge, regard this as the sole cause of kwashiorkor What other causal factors there may be is not known, the workers in Uganda regard skimmed milk as the treatment of choice, and do not feel that either choline or vitamin B_{12} has any specific therapeutic action Vitamin B_{12} may, however, play a supplementary part in preventive diets based on vegetable proteins To elaborate such diets is a problem of urgent importance, since, although in theory kwashiorkor could be eradicated by the provision of cow's milk, in practice there is not enough to go round As P GYORGY (Philadelphia) pointed out, the most economical source of protein for the infant is human milk Normally it is thought that if a diet is to be adequate at least 14% of its calories must be derived from protein In human milk this figure is only 6%, and yet it is a complete food—a very remarkable fact

Two papers were devoted to the metabolic and biochemical changes in human fatty liver and cirrhosis J C WATERLOW and S J PATRICK (University College of the West Indies Jamaica) have studied in infants the activity of a number of enzymes in liver tissue obtained by needle biopsy Although the results so far are negative, in the sense that no specific biochemical lesion has been found in the malnourished liver, it has been shown that this approach is technically feasible, it is possible to do six or seven different enzyme assays together with a number of other chemical measurements, on 3–4 mg of tissue These workers have found that the pattern of enzymes in the human liver is very different from that in the rat, which makes caution necessary in applying to one species conclusions derived from the other The enzymes that they have studied are very well preserved even in the most severely fatty livers nor have they been able to find any relation between the amount of fat in the liver as measured quantitatively in the biopsy specimen, and the general condition of the baby or its response to treatment These findings support the clinical conclusion of Trowell and others that in kwashiorkor the fatty liver is not the dominant feature

An enzyme that might well repay study in malnourished persons is xanthine oxidase W W WESTERFELD (Syracuse) described experiments in which the concentration of this enzyme in liver and gut was reduced almost to zero by protein starvation Moreover, for full activity xanthine oxidase needs a cofactor which has been identified independently by Westerfeld and by a group at the Lederle Laboratories as molybdenum This is of interest, since many tropical soils are deficient in that, as in other, trace elements The possibility of a trace element deficiency in man has been little investigated It may be that such a deficiency would manifest itself by a change in activity of enzyme systems many of which need metals in minute amounts either as activators or as constituents of prosthetic groups

Negative results were also reported by G J GABUZDA and C S DAVIDSON (Boston) from a study of nitrogen metabolism in patients with cirrhosis They could find no deviation from normal in nitrogen absorption, nitrogen balance, or amino acid tolerance Possibly these investigators were thwarted in their search for a metabolic disturbance by the enormous functional reserve of the liver If these two studies—that on nitrogen metabolism and that on enzymes—are representative, it must be admitted that we have a long way to go before we can characterise in biochemical terms either the lesion in the liver itself or its effect on the rest of the body

The last three papers of the first day were devoted to alcoholism and its treatment J MARDONES (Santiago, Chile) discussed the complex causal relations that may exist between alcoholism and vitamin deficiency First, alcohol, either by a pharmacological action or by increasing the calorie intake, may reduce the appetite there is no evidence that it causes an increased vitamin requirement Secondly, both Mardones and R J WILLIAMS (University of Texas) have shown experimentally in rats that deficiency either of known B vitamins or of some unknown factor may cause an increased craving for alcohol When vitamins are given, this craving disappears Lastly, both clinically and experimentally there seem to be great individual differences in the desire for alcohol These differences may result from a genetically determined disorder of metabolism, perhaps a difficulty in the initial stages of carbohydrate oxidation Thus, in Williams's view alcoholism results from a deviation, inherited or acquired, in nutritional requirements and metabolic pattern from that which we have come to regard as normal His approach can be followed in the study of any disease, not only alcoholism an emphasis on the importance of individual variability, which should be regarded not as an unavoidable evil, but as a focal point for research

Liver Necrosis

On the second day of the conference, when dietary liver necrosis was discussed, all the papers were concerned with experimental work, since there is no evidence that in man this lesion arises from malnutrition alone Nevertheless, it is possible that human dietaries may be lacking in some of the factors deficiency of which causes liver necrosis in rats Although in man this deficiency may never culminate in massive necrosis, it may be enough to make the liver more vulnerable to other insults, such as infections or toxins This point of view which dates back to the early work of Whipple, derives support from the experiments of P GYORGY (Philadelphia) He has shown that antibiotics notably aureomycin, confer a partial protection, delaying the onset of liver necrosis The inference is that bacteria from the gut play some causal part A crucial experiment on this point is now in progress, and was described by T D LUCKEY, of the Germ-free Laboratory, Notre Dame University Indiana Preliminary trials show that Gyorgy's necrogenic diets do not produce liver damage in rats which throughout their lives are kept germ free

of 60 ft. straight past number two; fortunately their belay held firm, and he was left swinging in the abyss.

At that distance his movements were reminiscent of those of a water-boatman (*Corixa geoffroyi*) and at the third swing he made contact with the rock and continued his upward course. At this point number two's voice, quite unruffled, floated across the corrie: "Ye' maun go it again, Jimmy; me, I couldna' manage." Jimmy went it again, this time with success; but, as I strolled round to the top of the climb, I saw both number two and number three miss their footing at the mauvais pas, and swing similarly for a time, though on a shorter pendulum, in space. When eventually they all came over the lip of the crag, I inquired whether they had had an enjoyable climb. "Ach fine," they said.

Then number three, who took blackouts, was a cause of some concern even to the Hasheaters; but I have since heard with relief that he is now safely in the Royal Air Force.

Did general practitioners contribute more to advances in medicine in the past than the present? I found myself pausing in my researches among the medical journals of last century to ask this question. I opened my mouth to say "Yes, of course," and then I stopped to reflect. I am glad I did so, for I would otherwise have fallen into the ever-open trap, better recognised by statisticians than by us lesser mortals, of comparing incomparables.

General practice and its place in medicine have greatly changed during the past century. A hundred years ago consultants with hospital beds had no particular advantage over general practitioners in their opportunities for advancing medical knowledge. But today specialists (the term now seems more appropriate than consultants) have access to many facilities denied to the general practitioner—junior staff, records staff, first-class nursing, a laboratory, an X-ray department, and so on. But the general practitioner is not without his own advantages; he can still advance knowledge by clinical study of the natural history of diseases, especially short-term febrile illnesses seldom seen in hospital practice, and by study of familial, social, and environmental aspects of disease. His better title—family doctor—shows where his real opportunities lie.

Many commemorative lectures tail off towards the end and we are brought back to consciousness by the handclaps of those in the front row. How pleasant it was by contrast the other evening when, at the end of his discourse, the lecturer turned from the discussion of diseases of an important organ to recall how when he was a little boy his father used to entertain him and his small friends to a magic-lantern show in the consulting-room. The lecturer has treasured ever since one of the slides which ended these shows, and he now had pleasure in putting it on the screen. It was a picturesque scene such as would appeal to the young of all ages, and across the top of it in beautiful lettering were the words "Good Night." I shall remember this when I have long forgotten what the lecture was about.

* * *

The other day I came across this inscription in Southwark Cathedral:

> Here Lockyer lies interr'd: enough, his name
> Speakes one hath few competitors in fame;
> A Name soe Great, so Generalle may scorne
> Inscriptions wh. doe vulgar tombs adorne.
> A diminution tis to write in verse
> His eulogies wh. most mens mouths reherse.
> His virtues and his PILLS are soe well knowne
> That envy can't confine them under stone.
> But they'll survive his dust and not expire
> Till all things else at th' universall fire.
> This verse is lost, his PILL Embalmes him
> To future times without an Epitaph.
> This April 26, 1672, aged 7[illegible]

I wonder who Lockyer was, and whether his pills still survive under different names to the Universal Fire.

* * *

I wonder what river my fellow peripatetic of March 28 was fishing when he saw a pair of yellow wagtails disporting themselves on the bank beside him. The yellow wagtail is not usually a water bird, and it is surely quite an ornithological event for him to be seen in this country before the end of March.

Letters to the Editor

PHARMACEUTICAL ADVERTISEMENTS

SIR,—The letter from Dr. Elek (March 28), written apparently with authority from St. George's Hospital Medical School, is so seriously misinformed that a reply is needed. He complains that British pharmaceutical firms are not fair or just—he even uses the word pernicious—because they do not return financial rewards to medical research. Has he bothered to confirm his facts? Does he know, for example, that one alone of these firms spends half a million pounds every year on medical research?

He urges, as if it were a new idea, that manufacturers should "spend at least part of their profits on financing research projects in universities and other suitable establishments—not in their own laboratories where a bias could be suspected." Does he know that approximately 100 research fellowships in universities are maintained by these British commercial firms with complete freedom from control; and that one single firm makes grants to other research workers in universities of well over £100,000 a year? Does he know that these firms are promoting a department of pharmacology in the Royal College of Surgeons of England at a cost of many thousands of pounds, again with complete freedom to the college?

And finally—this really is the last straw—he compares British firms unfavourably with American firms in their devotion to advertisement rather than to research. I would like to be kind to Dr. Elek, but surely never before did misinformation lead to such wanton misrepresentation.

London, W.1. REGINALD WATSON-JONES.

FLOUR

SIR,—The explanations offered by Professor Frazer (March 28) for our patient's allergic response to chemically treated flour appear to be based on the assumption that the flour or bread this patient was given had always received either chemical or physical (aeration) treatment.

Whereas the use of flour improvers is a miller's process, the aeration treatment is a baker's process, applied during the making of the dough. It was stated in our paper that the patient was given a 7 lb. bag of chemically untreated flour for cooking purposes. This flour had received neither chemical nor physical (aeration) treatment. She consumed the whole 7 lb. of flour with no skin disturbance. Moreover, since then she has used four more 7 lb. bags of chemically and physically untreated flour for cooking. The products have been shared with her family, but she estimates that she has eaten about one third (or 9 lb.) of the flour herself, and there has been no reaction in her skin.

Since Dr. Frazer's letter appeared, the patient has been given bread made by the straight dough process (i.e., without aeration) from chemically untreated flour. Her skin has shown no reaction to this bread.

Reigate. G. C. SHELDON.
London, W.1. ALLAN YORKE.

SIR,—At the end of their article of March 21, describing a case of eczema associated with the ingestion of chemically "improved" flour, Dr. Sheldon and Dr. Yorke pose the question: "Is this a rare case of allergy, or merely the first recognition of a common disorder?" The following is an account of an almost exactly similar syndrome whose association with flour I recognised in 1946 but which hitherto I have not reported publicly.

A married housewife, then aged 41, developed in December, 1942, a severe facial eczema. (In contrast to Sheldon and Yorke's case, the extremities were not affected. The menopause did not occur till ten years later.) In its most developed form the eczema occurred in phases, or cycles, which had a periodicity of about 7–9 days. The onset of each phase was characterised by a sense of localised prickling and tightness. In about 24 hours angry red splashes appeared symmetrically where mother and infant carried staphylococci, the type was the same in 19.

Ludlam concludes that, though some of the observations are difficult to explain, there is little evidence of transfer of nasal staphylococci from the mother to the infant in hospital, but that [illegible] staphylococci are liable to be acquir[illegible]ant. The hospital-delivered mother probably picks up the resistant strain from her infant after her return home. There is also some risk that penicillin-resistant strains may be further spread in the community by transfer to home-born infants at the clinics or possibly by midwives recently associated with the hospitals. Resistant strains do not yet seem to be becoming much more prevalent in the general population; but it is important to watch the routes by which such prevalence may be increased.

INSURANCE CLAIMS AND INFLUENZA

THOSE who have laboured to produce statistics of weekly claims on the Ministry of National Insurance for sickness benefit probably never dreamt that their figures would be useful to students of the epidemiology of influenza. Today almost all who earn are entitled to sickness benefit; and during an epidemic of influenza, particularly one caused by virus A, the usual high incidence of infection is rapidly reflected in a sharp rise in the claims for sickness benefit. No other disease produces a comparable rise in morbidity figures; and a rise in the number of claims above 175% of the weekly average can be taken as evidence of influenza. By following the rise and fall in the figures for claims in different parts of the country the path of an influenza epidemic can be accurately mapped out.

This technique was first successfully applied in the 1950–51 epidemic of influenza,[1] where it was shown that the outbreak began in three port areas—Aberdeen, Tyneside, and Falmouth-Truro—and was followed by an independent focus in Merseyside. Corresponding information for this year's epidemic is not yet available, but a recent report[2] summarises some essential features shown by preliminary figures. In the first week of January of this year influenza had reached a moderately heavy prevalence in two areas—the Eastbourne district, and an area which contains many Service establishments and stretches from Camberley, Aldershot, and Farnham up to the Thames between Egham and Walton. The London area became involved in the third week of January, and thereafter the epidemic wave spread outwards from London growing fainter as it spread further north. There is a clear indication that areas heavily involved in 1950–51 were dealt with more leniently in the present epidemic. If we take the hint, protective vaccination for the next epidemic should be concentrated on populations in the Midlands and further north who were less densely infected this year.

Each new successful technical advance seems to answer some of the questions for which it was designed and then to pose new problems. One problem brought out by the investigation of the 1950–51 outbreak was the strange way in which the epidemic seemed to advance across country like a wave, ignoring the well-worn lines of communication. This unusual type of progress has been reported before, and there seems at present to be no obvious explanation. Another problem concerns the origin of this year's epidemic; the early involvement of port areas in the 1950–51 epidemic showed that virus had entered this country by sea—a fact that was strongly supported by antigenic studies of viruses isolated here and abroad. This year, however, the epidemiological data suggest either that the virus had sneaked quietly into the country and waited for a favourable moment, or that it had remained in this country in a latent phase during the past two years. Epidemiologists would much like to know by which of these ways the epidemic originated.

A RARE COMPLICATION OF CHICKENPOX

Saslaw and his colleagues[1] at the Ohio State University Hospital have recently, within a period of five months, seen 3 adults with chickenpox and associated pneumonia. Radiographs of the chest in each case showed diffuse bilateral nodular or miliary infiltration, scattered evenly throughout both lung fields. Radiographic clearing ran parallel with the improvement of the skin lesions, although in 1 patient some infiltration was still present in the lower lobes two months after the onset of the pneumonia. Blood-cultures were negative in every case. Results of sputum examinations did not suggest a bacterial pneumonia. The leucocyte-count was only moderately elevated in 2 patients and was normal in the 3rd. Serological investigation for primary atypical pneumonia, psittacosis, and Q fever was negative. The clinical and radiological features in the 3 patients were closely similar. The pneumonic illness was in each case severe, and although dramatic recovery took place, this was not attributed to any specific action of antibiotics on the varicella virus. The authors could find only 8 similar reported cases—all in adults in the United States.

NEW REGULATION

THE new arrangements proposed by the Working Party[2] for distributing the central pool to general practitioners in the National Health Service came into force on April 1. The principal [illegible] the increase of the capitation fee to [illegible]; [illegible] of the maximum size of a doctor's list from 4000 to 3500; and an extra payment of 10*s.* for each patient from the 500th to the 1500th on a doctor's list. Doctors with 4000 patients will have twelve months in which to adjust their lists. Initial allowances[3] (£600 in the first year, £400 in the second year, and up to £200 in the third) have been introduced to encourage doctors to set up in practice in under-doctored areas. Hardship allowances will be available for elderly doctors who may lose their "fixed annual payment" and not be eligible for the new initial allowance. Doctors of sixty-five and over with lists of at least 500 persons may claim these supplementary payments which will not exceed £350 per annum; claims should be submitted if possible by June 30. Full details of the scheme were issued to executive councils last week.[4]

The regulations officially making these charges were published on March 27. (The allocation of the sum reserved by the Working Party for stimulating the growth of group practices is still under consideration.) It is unlikely that they will be challenged; but a group of Labour M.P.S. headed by Mr. Aneurin Bevan, have tabled a prayer for the annulment of the rules issued last month[5] amending the cost of pay-beds and the medical and surgical fees for private patients.

ON March 30 Sir RUSSELL BRAIN was re-elected president of the Royal College of Physicians of London.

THE 121st annual meeting of the British Medical Association will be held in Cardiff from July 9 to 17 under the presidency of Mr. Tudor Thomas. Coronary Disease, Fibrositis, and Overweight have been chosen as the subjects of the three plenary scientific sessions.

the available evidence is consistent with it Otherwise, the pharmacopœia would be burdened with every new "remedy" which was not proved to be actively harmful We have found no evidence that vitamin E increases the exercise tolerance of patients with intermittent claudication, and we have shown that its possible effect under the conditions of our trial is at most, small We believe, therefore, that the null hypothesis should be assumed to be true

SENIOR REGISTRARS

SIR,—It is time that something was done to help senior registrars who cannot help themselves There must be many hundreds of us throughout the country, growing yearly more hopeless a stagnant pool of cheap specialists deliberately created by the National Health Service A great many of us have been qualified for more than twelve or fourteen years, but we are paid less than newly settled general practitioners, we are liable to dismissal at short notice and at regular intervals, we cannot settle anywhere and we cannot plan anything Successive Ministers of Health or their underlings have blandly assured us for years that they are deeply concerned and the position is being explored

It is obvious that we cannot all become consultants overnight—indeed some of us may never be suitable But two immediate measures could be adopted to help us meet our financial and domestic insecurity We could be given some certainty of tenure of our posts beyond three years, and we could be given some annual increment of pay when we have reached the present maximum of £1300, which is so very much less than that of the most recently appointed consultant

Ipswich EDWARD ELMHIRST

POSITION FOR TONSILLECTOMY

SIR,—I would like to comment on the remarks of *Mr Ballantyne and Dr MacDermott (March 14)*

Although the risk of spinal-cord damage during tonsillectomy must be extremely remote, the cases cited by Sir Charles Symonds are a warning against hyperextension of the neck As your correspondents point out, the reason for the extended position is to prevent blood entering the bronchial tree St Clair Thomson and Negus[1] say that 40% of a series of post tonsillectomy cases were found to have blood in the bronchi Yet pulmonary complications from this cause are rare it is probable that they occur *only after the inhalation of tonsillar* tissue or blood clot Small quantities of blood entering the trachea in a liquid form will be spread over the surface in a thin film and removed by ciliary action before bronchial plugging occurs Thus, the risk is slight if flooding of the laryngeal opening during the operation is prevented, if complete hæmostasis is attained, if all blood clots are removed from the nasopharynx and pharynx at the end of the operation, and if the patient is rapidly moved to the lateral position Flooding of the laryngeal opening can be prevented by intratracheal intubation with a large-bore tube and by the use of an efficient suction apparatus by an assistant if the hæmorrhage is brisk *Hyperextension of the neck* is not necessary In my experience the use of a pillow under the shoulders is liable to cause excessive extension in short necked subjects My practice is to lower the head rest, after the patient has been placed on the table and a gag inserted to an angle just sufficient to cause the blood to drain away from the larynx In all but the rare case no strain on the neck results, particularly if the anæsthesia is on a light plane In the rare case, some degree of Trendelenburg position can be added The careful removal of clots at the end of the operation is probably of greater importance in the prevention of pulmonary complications than the degree of hyperextension of the neck I know of a near fatality caused by laryngeal occlusion by a large clot dislodged from the nasopharynx after the patient was moved from the table

Finally, I consider that there is some risk of injury to the neck when the patient is moved from the table and turned on his side

REMEDY FOR ANÆMIA

SIR,—It is with regret that I note in your column an advertisement for a new hæmatinic which recalls the palmy days of polypharmacy It is said that each capsule of this preparation contains 192 mg ferrous sulphate, 10 µg vitamin B_{12}, 0 85 mg folic acid, 50 mg ascorbic acid, 100 mg powdered stomach and 350 mg of an insoluble liver fraction, and it is recommended as "*the greatest step forward yet made in the treatment of common anæmia*," and "invaluable in the treatment of nutritio[illegible] post-infectious anæmia, the [illegible] of pregnancy, infancy, pellagra and sprue and allied dyscrasias"

Whatever may be the situation in the United States, this polypharmacy is not needed in Britain The megaloblastic anæmias of pregnancy, infancy, pellagra and sprue are so rare that full scale investigation is needed before any such diagnosis can be accepted treatment may then be with folic acid, vitamin B_{12} and ascorbic acid, nicotinic acid, &c, whichever is indicated Nutritional hypochromic anæmia—an elegant term for iron deficiency—can be treated quite efficiently by simple iron salts or by injection of saccharated iron hydroxide

Further, such blunderbuss preparations are dangerous, because they prevent accurate diagnosis Only the other day I was asked to study an anæmic patient who had received iron salts, folic acid, liver extract (parenteral and *oral*), vitamin B_{12}, and a mixture of other B vitamins This treatment had effectually destroyed the clues on which I depend, and I could not help the patient Another patient, referred to a colleague for diagnosis of a suspected pernicious anæmia, received *oral* and parenteral liver extract only 24 hours before reference *to hospital for* investigation—making the diagnosis unnecessarily difficult No one can exaggerate the importance of diagnosis in anæmia, or the difficulty of establishing it after treatment has started In more than 9 cases out of 10, a simple history and simple laboratory tests suffice to establish the diagnosis—and laboratory tests are becoming available to more and more practitioners

One must conclude that the manufacturers of the new confection are hoping to divert a larger proportion of the nation's drug bill into their own *pockets* This is a lawful—and perhaps even a *commendable*—aim but the money available for the health service is limited and the cost of curing a patient with the new remedy is likely to exceed that of curing him with some simpler and less elegant preparation It is difficult to escape the conclusion that to order so elegant a preparation is against the best interests of patients and of the country

Such sentiments are spreading among the younger consultants and their registrars Our task today is to restore to health (and work) as *many patients* as possible and to do this at the minimum of expense Recently it was pointed out that about £240 000 has been wasted by *ordering a proprietary* preparation in place of its official equivalent *d* amphetamine

When public moneys are wasted on this scale those who encourage such expenditure are challenging the Government of the day, one of whose chief tasks is to cally the important route of spread. Moreover, indirect evidence, obtained from attempts to prevent "airborne" spread by way of droplet nuclei and dust, suggests that, at most, such spread is of only secondary or minor importance. Repeated attempts to control the environment with ultraviolet light, aerosols, and the oiling of floors and blankets have had little effect on the spread of hæmolytic streptococci or of other forms of respiratory disease.[11 12] It may be argued that all important places of spread have not been controlled in such studies, but the fact remains that these procedures, as used, have not been effective.

The hypothesis that seems most tenable is that intimate contact, such as occurs, for example, in the home and possibly in the school-room, is required for effective spread. Elucidation of the factors involved in intimate contact is difficult, but it seems reasonable that physical contact and transmission by larger droplets for short distances are operative. Presumably time-dosage relationships are important. Transmission may be effected along single or multiple channels which are not yet defined.

There are, of course, other factors that correlate with the occurrence of group-A streptococcal infections, such as age, climate, season, and degree of crowding. Such correlations have been given causal significance in the past, but it now seems desirable to re-examine their interpretation. For example, the age-specific incidence-rates for streptococcal infections, usually greatest in the age-group 5–9 years, primarily may reflect not susceptibility but simply the opportunity to acquire infection. In a study of illness in Cleveland families[13 14] the peak of all respiratory infections was in young school-children. Moreover the height of the attack-rate in pre-school children depended on the presence or absence of school-age siblings in the home. Thus the level of occurrence of respiratory illnesses in the pre-school child depended primarily on his opportunity to acquire infection from an older sibling. Likewise the high infection-rates which have persisted for years at certain military posts may indicate that the troops at such posts have a greater opportunity to acquire streptococci and not that the troops stationed there have an increased innate susceptibility. A true interpretation remains to be established.

Similarly, correlations of infection-rates and carrier-rates with climate, season, and crowding may reflect merely the relation of these factors to the opportunity to acquire and carry the streptococcus, rather than the more subtle effects of these factors on the organism or the host. Thus, in the study of 53 "convalescent carriers" mentioned previously, 27 were transported by airplane to the Florida coast and the remaining 26 were kept at the 6000-ft. altitude of Cheyenne, Wyoming.[4] The number of streptococci decreased at the same rate in these two groups of carriers. Here, at least, geographic location and the differences in climatic conditions, comparable to seasonal change, did not affect the quantitative aspects of the host-parasite relation during convalescence.

For reasons such as these it seems desirable to re-examine our accepted concepts of the epidemiology of β-hæmolytic streptococcal infections and, in so doing, to seek fuller interpretations of the importance and significance of factors apparently related causally to high or to low incidence and prevalence levels.

Non-suppurative Complications of Group-A Streptococcal Infections

It is now generally accepted that there is a temporal and probably causal relation between group-A streptococcal infections and rheumatic fever. In contrast, the relation between streptococcal infection and acute hæmorrhagic glomerulonephritis has been less definite. If the association of rheumatic fever and nephritis with streptococcal infections is truly one implied by the term "non-suppurative complications," that association should be supported by a consideration of the epidemiological aspects of both the initial infection and of the complicating sequelæ.

RHEUMATIC FEVER

There now seems to be little question of the relation of a group-A streptococcal infection, or perhaps of multiple infections, to the development of rheumatic fever. Justification for this conclusion comes from such evidence as: (1) the serological demonstration of type-specific streptococcal infection preceding the onset of rheumatic fever in the individual case[15]; (2) the epidemiological association of "outbreaks" of rheumatic fever with outbreaks of streptococcal disease[16]; and (3) the virtual eradication of rheumatic fever by prophylaxis or early treatment of streptococcal infections.[15–18]

Moreover the epidemiological features of rheumatic fever may be likened to those of group-A streptococcal infections, when such factors as age, season, climate, geographic distribution, and crowding are considered. Until established beyond reasonable doubt, however, it does not necessarily follow that similarities with respect to such factors prove that the two types of illness are causally related. But closer inspection of these factors in the light of the available data leads to the concluson that the epidemiological features of rheumatic fever are indeed those of group-A streptococcal infections in general.

Rheumatic fever, for example, is principally a disease of childhood. The assumption has therefore been made that children are more susceptible to rheumatic fever than are adults, and that such susceptibility explains the age-distribution. Yet, when streptococcal infections occur in young adults, as in the military forces,[19] the incidence of subsequent rheumatic fever is not significantly different from that occurring after streptococcal infections in children—i.e., about 3%. Therefore susceptibility to rheumatic fever does *not* appear to decrease with age, at least during the first three decades. If one now compares the age-distributions of streptococcal infections and of rheumatic fever in civilian populations, one finds that they can be superimposed, and that the peaks of both are in the same age-group of 5–9 years. Thus the relation of age to the occurrence of rheumatic fever is the same as the relation of age to streptococcal infections.

Geographic distribution provides another example, although the data are more limited. The areas of high prevalence of rheumatic fever are usually those having a high prevalence of streptococcal infections. Moreover, the frequency of occurrence of rheumatic fever as a complication of group-A streptococcal infections, regardless of the route of transmission, is about 3% in Boston,[20] North Carolina,[21] Wyoming,[19] Denmark,[22] and other areas.[19]

As regards the relation of housing and poverty to the recurrence of rheumatic fever, Hewitt and Stewart[23] obtained no evidence that the disease was associated either with bad housing or with poverty per se. They pointed out that the opportunity for infection appeared to be the overruling factor determining its incidence.

In further support of the close epidemiological association of rheumatic fever and group-A streptococcal infections in general is the fact that rheumatic fever follows streptococcal infection without apparent regard for the type-specificity of the infecting streptococcus.

ACUTE GLOMERULONEPHRITIS

The relation of acute hæmorrhagic glomerulonephritis to infection with β-hæmolytic streptococci has not been as clear, nor as generally accepted, as the association the available evidence is consistent with it Otherwise, the pharmacopœia would be burdened with every new "remedy" which was not proved to be actively harmful We have found no evidence that vitamin E increases the exercise tolerance of patients with intermittent claudication, and we have shown that its possible effect under the conditions of our trial is at most, small We believe, therefore, that the null hypothesis should be assumed to be true

SENIOR REGISTRARS

SIR,—It is time that something was done to help senior registrars who cannot help themselves There must be many hundreds of us throughout the country, growing yearly more hopeless, a stagnant pool of cheap specialists deliberately created by the National Health Service A great many of us have been qualified for more than twelve or fourteen years, but we are paid less than newly settled general practitioners, we are liable to dismissal at short notice and at regular intervals, we cannot settle anywhere and we cannot plan anything Successive Ministers of Health or their underlings have blandly assured us for years that they are deeply concerned and the position is being explored

It is obvious that we cannot all become consultants overnight—indeed some of us may never be suitable But two immediate measures could be adopted to help us meet our financial and domestic insecurity We could be given some certainty of tenure of our posts beyond three years, and we could be given some annual increment of pay when we have reached the present maximum of £1300, which is so very much less than that of the most recently appointed consultant

Ipswich EDWARD ELMHIRST

POSITION FOR TONSILLECTOMY

SIR,—I would like to comment on the remarks of Mr Ballantyne and Dr MacDermott (March 14)

Although the risk of spinal cord damage during tonsillectomy must be extremely remote, the cases cited by Sir Charles Symonds are a warning against hyperextension of the neck As your correspondents point out, the reason for the extended position is to prevent blood entering the bronchial tree St Clair Thomson and Negus[1] say that 40% of a series of post tonsillectomy cases were found to have blood in the bronchi Yet pulmonary complications from this cause are rare it is probable that they occur only after the inhalation of tonsillar tissue or blood clot Small quantities of blood entering the trachea in a liquid form will be spread over the surface in a thin film and removed by ciliary action before bronchial plugging occurs Thus, the risk is slight if flooding of the laryngeal opening during the operation is prevented, if complete hæmostasis is attained, if all blood clots are removed from the nasopharynx and pharynx at the end of the operation, and if the patient is rapidly moved to the lateral position Flooding of the laryngeal opening can be prevented by intratracheal intubation with a large bore tube and by the use of an efficient suction apparatus by an assistant if the hæmorrhage is brisk Hyperextension of the neck is not necessary In my experience, the use of a pillow under the shoulders is liable to cause excessive extension in short necked subjects My practice is to lower the head rest after the patient has been placed on the table and a gag inserted to an angle just sufficient to cause the blood to drain away from the larynx In all but the rare case no strain on the neck results, particularly if the anæsthesia is on a light plane In the rare case some degree of Trendelenburg position can be added The careful removal of clots at the end of the operation is probably of greater importance in the prevention of pulmonary complications than the degree of hyperextension of the neck I know of a near fatality caused by laryngeal occlusion by a large clot dislodged from the nasopharynx after the patient was moved from the table

Finally, I consider that there is some risk of injury to the neck when the patient is moved from the table and turned on his side

Swindon Wiltshire COLIN M JOHNSTON

REMEDY FOR ANÆMIA

SIR,—It is with regret that I note in your columns an advertisement for a new hæmatinic which recalls the palmy days of polypharmacy It is said that each capsule of this preparation contains 192 mg ferrous sulphate, 10 µg vitamin B_{12}, 0 85 mg folic acid, 50 mg ascorbic acid, 100 mg powdered stomach, and 350 mg of an insoluble liver fraction, and it is recommended as "the greatest step forward yet made in the treatment of common anæmia" and "invaluable in the treatment of nutritional hypochromic anæmia post-infectious anæmia, the megaloblastic anæmias of pregnancy, infancy, pellagra and sprue and allied dyscrasias"

Whatever may be the situation in the United States this polypharmacy is not needed in Britain The megaloblastic anæmias of pregnancy, infancy, pellagra and sprue are so rare that full scale investigation is needed before any such diagnosis can be accepted, treatment may then be with folic acid, vitamin B_{12} and ascorbic acid, nicotinic acid, &c, whichever is indicated Nutritional hypochromic anæmia—an elegant term for iron deficiency—can be treated quite efficiently by simple iron salts or by injection of saccharated iron hydroxide

Further, such blunderbuss preparations are dangerous because they prevent accurate diagnosis *Only the other day I was asked to study an anæmic patient who had received iron salts, folic acid, liver extract (parenteral and oral), vitamin B_{12}, and a mixture of other B vitamins This treatment had effectually destroyed the clues on which I depend, and I could not help the patient Another patient, referred to a colleague for diagnosis of a suspected pernicious anæmia, received oral and parenteral liver extract only 24 hours before reference to hospital for investigation—making the diagnosis unnecessarily difficult No-one can exaggerate the importance of diagnosis in anæmia, or the difficulty of establishing it after treatment has started In more than 9 cases out of 10 a simple history and simple laboratory tests suffice to establish the diagnosis—and laboratory tests are becoming available to more and more practitioners*

One must conclude that the manufacturers of this new confection are hoping to divert a larger proportion of the nation's drug bill into their own pockets This is a lawful—and perhaps even a commendable—aim, but the money available for the health service is limited and the cost of curing a patient with the new remedy is likely to exceed that of curing him with some simpler and less elegant preparation It is difficult to escape the conclusion that to order so elegant a preparation is against the best interests of patients and of the country

Such sentiments are spreading among the younger consultants and their registrars Our task today is to restore to health (and work) as many patients as possible and to do this at the minimum of expense Recently it was pointed out that about £240 000 has been wasted by ordering a proprietary preparation in place of its official equivalent, *d* amphetamine

When public moneys are wasted on this scale those who encourage such expenditure are challenging the Government of the day, one of whose chief tasks is

Medical Conferences

NUTRITIONAL FACTORS AND LIVER DISEASES

Conference in New York

FROM A CORRESPONDENT

The biology section of the New York Academy of Sciences on Feb. 13 and 14 held a conference under the chairmanship of Dr. Klaus Schwarz, with the ambitious object of reviewing modern knowledge on dietary liver injury, and particularly the relation of animal experiments to conditions in man. Progress in the study of liver disease is especially notable in the tropics, where diets are poor and malnutrition comes high on the list of suspects as a cause of liver damage. For this reason the Academy generously made it possible for several workers from overseas to attend the conference. Nevertheless, the main emphasis was inevitably on experimental work: of 27 papers, only 7 dealt with liver disease in man. In the printed report, however, the balance will be restored by the inclusion of communications from J. N. P. Davies (Uganda), J. Gillman and T. Gillman (Johannesburg), and B. M. Nicol (Nigeria).

Fatty Liver and Cirrhosis

In an introductory paper F. S. Daft (National Institutes of Health, Bethesda) emphasised the differentiation, first made by the workers at Bethesda, of two completely distinct pathological entities: on the one hand fatty liver, caused by deficiency of choline or its precursors, and leading ultimately to cirrhosis; on the other hand *necrosis resulting from deficiency of sulphur-amino-acids.*

C. H. Best (Toronto) discussed the nutritional significance of choline, and suggested that the term "lipotropic" should be restricted to describe substances which accelerate the rate of removal of excess liver fat; it cannot logically be applied to the other effects of choline, such as the prevention of hæmorrhagic kidneys in growing rats, or of slipped tendons in chicks. Choline has been shown to have lipotropic activity in a wide variety of animal species, but whether the list includes man is not yet certain. Even in animals it is difficult to produce a diet deficient only in lipotropic factors, because of the dual rôle of methionine as a precursor of choline and as an essential sulphur-containing amino-acid. In man the difficulties are even greater, and the crucial experiment to test the lipotropic effect of choline has not yet been performed.

This point recurred in a later paper by G. J. Gabuzda and C. S. Davidson (Boston), on the treatment of alcoholic cirrhosis. This disorder responds well to dietary treatment in hospital; the improvement cannot be attributed simply to hospitalisation and withdrawal of alcohol because it does not occur when only glucose-saline is given. The results of adding choline to the glucose-saline were *not impressive.* This experiment, however, does not fulfil the criterion that the diet should be deficient only in lipotropic factors and in nothing else.

It was clear from subsequent papers that we have still much to learn about the mechanism of lipotropic activity. Two lines of approach have a fundamental bearing on this problem. One is to study the mechanism of transmethylation and the metabolism of one-carbon compounds. This topic was touched on, but not developed in detail, in discussion of a paper by V. A. Drill (Wayne University, Detroit). His work re-emphasises the point originally developed by McHenry—that the lipotropic effect of various substances does not depend only on their choline content. Drill has shown that liver extract has a greater lipotropic activity than stomach powder, although the latter contains much more choline. Liver extract contains vitamin B_{12} and folic acid, both of which play some part in transmethylation reactions. These vitamins by themselves had *no lipotropic action under* the conditions of his experiments; but together, in combination with small amounts of choline, they were partially though not completely effective. Drill suggests that liver extract may contain some as yet unidentified lipotropic factor; it may be this that is responsible for the beneficial effect of milk in human fatty liver (kwashiorkor), in which choline and methionine are, from all reports, ineffective.

The second approach to the problem is the measurement of turnover-rates under various dietary conditions. W. E. Cornatzer (University of North Dakota) has studied this problem extensively. He described phospholipid synthesis in the liver as a very primitive function only altered by severe stress. In man the rate of synthesis is very little changed in cirrhosis or hepatitis; in animals it appears to be constant, whether the liver is fatty, fibrosed, or normal, and is not affected by the dietary protein intake. According to the classical theory, choline deficiency causes fatty liver by slowing down the formation of phospholipids and hence causing a failure of fat transport. Turnover studies appear not to support this view, although the intricacies of this experimental approach are not readily grasped by the uninitiated, who include your correspondent.

From biochemistry the conference went on to consider the sequelæ of fatty liver, and the long-term results of the diets which produce it. The histogenesis of fibrosis was described by W. S. Hartroft (Toronto). An important transition stage is the formation of fatty cysts by the fusion of cells overloaded with fat. This paper produced some interesting topics for discussion. The general feeling seemed to be that there is not sufficient evidence to postulate an invariable causal relationship between fat and fibrosis, although the degree of fatty change is very important. It is a puzzling fact, and one not sufficiently appreciated, that whereas in the rat both fat and fibrosis appear first and are most severe at the centre of the lobule, in man—at least in kwashiorkor—both lesions begin peripherally. Whatever the reason for this difference, it is noteworthy that in both species the fibrosis develops at the site of the fatty infiltration. There is no preceding necrosis in the usual sense of the word; but the presence of fatty cysts, produced by rupture of cell-membranes, is evidence that those cells which have fused were degenerate. Fibrosis or cirrhosis is not the only sequel of choline deficiency: as D. H. Copeland and W. D. Salmon (Auburn, Alabama) have shown, if sufficiently prolonged it leads to the formation of tumours, both benign and malignant, in the liver and other organs. J. W. Wilson (Brown University, Providence, Rhode Island) has also produced neoplasia in mice by feeding a base exchange silicate, which probably acts by removing choline from the intestinal contents.

The relevance of this experimental work to problems of human medicine and pathology was well illustrated by J. F. Brock (Cape Town). He presented maps showing the reported distribution, throughout the world, of kwashiorkor, cirrhosis of the liver, and primary hepatic carcinoma. Although the distributions seem not to be identical, all three conditions have a high prevalence in the tropics and in countries where *there is much* malnutrition. Reliable information about prevalence is, however, very scanty; Brock's paper emphasised the part that epidemiological studies can play in elucidating the pathogenesis of these forms of liver injury and their relation to diet.

Although information may be scanty from many parts of the world, this cannot be said of Uganda. From that territory outstanding contributions have been made to our knowledge of kwashiorkor, mainly through the work mechanism by which the results are achieved is often a matter for conjecture The important thing is to have achieved by manipulation the relief no other treatment could have produced

London, S W 3 JOHN EBBETTS

HALLUX VALGUS

SIR,—You have often commented on the high prevalence of hallux valgus (which even in school children is as great as 80%[1 2]) and you referred in your leading article of Feb 14 to the unsatisfactory results of treatment

For the past twelve years I have studied this condition in detail, and I should like to set out my conclusions on its cause, on the probable reasons for failures in treatment, and, most important, on how hallux valgus can be prevented

Cause

The normal hallux should be quite straight, and the angle of the metatarsophalangeal joint should be 180° But a normal hallux is rarely seen in the adult by the age of two 10% of children have a valgus deformity, and at sixteen the figure is 80%

The normal position is the position in which there is maximum efficiency in weight transmission This is the position the hallux will always assume when weight bearing, unless deformed or restricted by footwear The earliest sign of hallux valgus is slight adduction of the hallux when the foot is at rest and not weight bearing

Seat the patient so that his feet rest comfortably on the floor The toes are adducted, forming a slight angle instead of being in contact throughout their length When the patient stands up an inward thrust accompanies the well known forward thrust and corrects the deformity (fig 1) In early cases the correction is complete, but it becomes less and less effective as the deformity progresses

But this natural corrective action of the deformed foot is *not* possible in most kinds of shoe

Once the inward thrust becomes ineffective severe hallux valgus is inevitable *from this point onwards the foot deforms itself*

Hardy and Clapham[3] confirmed my view[1] that the cause of hallux valgus is not hereditary Hallux valgus can only be caused by wearing wrongly designed footwear The presence of some hereditary factor in no way alters this fact The only cause is pressure on the inner side of the phalanges which is greater than that exerted upon the inner side of the first metatarsal—in other words, a pressure that causes adduction of the hallux When the hallux is held for long periods in the adducted position a vicious circle is created which leads to considerable deformity

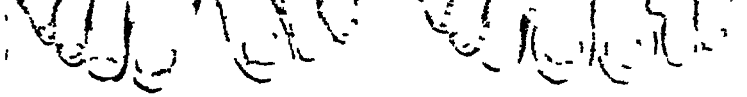

Fig 1—(Left) feet of 13-year-old child at rest showing 13° of hallux deformity (right) same feet when bearing weight, showing correction of deformity

Examination of all adults' and most children's footwear will show that it cannot accommodate the hallux in its normal position When the foot is shod the hallux is adducted

Adduction approximates the origin and insertion of the long flexors and extensors of the toe because they arise on the outer side of the long axis of the toe Prolonged adduction causes a shortening of these slackened structures which, when complete, alters the action of these muscles

In a normal foot or in one only slightly deformed, the command "bend your toes up or down" produces a pure flexion or extension of the toes As soon as shortening occurs pure movements are impossible Voluntary flexion and extension is thereafter always accompanied by adduction of the hallux The adduction producing a lateral movement of as much as half an inch

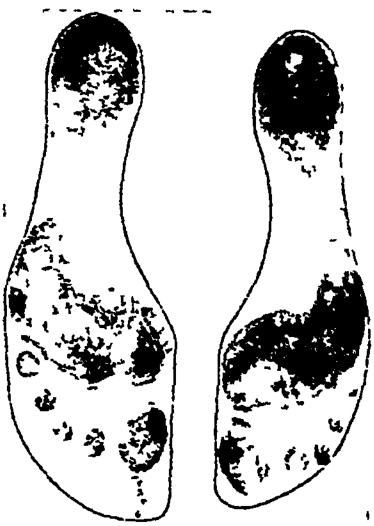

Fig 2—Correctly designed footwear Foot prints of a child with insole patterns superimposed Both shoes have a straight inner border and accommodate the toes in their normal position (Left) correct fitting with allowance for thrust and growth, (right) incorrect fitting

The abductor hallucis offers no effective opposition, and from this point onwards every movement of the hallux includes unopposed adduction and further shortening, leading to obvious valgus deformity Ultimately the degree of deformity exceeds that of the shape of the shoe

It is not generally realised how very early these changes occur There does not appear to be any fixed point beyond the 180° at which these changes commence X ray examination has shown that rearrangement of the trabeculæ of the cancellous bone of the hallux occurs quite early One case with only 18° of deformity showed a definite radiation pattern forming at the point where the exostosis later developed

Treatment

Cases can conveniently be divided into three groups self-correcting, correctable, and operation cases

Self-correcting—In early cases where an effective inward thrust is still present the provision of correctly designed footwear, permitting the toe to resume its normal position, will ultimately effect a cure

Correctable—Cases where the inward thrust, if present is ineffective, where there is no gross joint or bone change, and where with the aid of manipulation under anæsthesia, restoration of mobility and normal position are obtainable, can be corrected without operation These cases respond well to corrective strapping over a long period The strapping must maintain correction without restricting foot function and I have suggested a method of doing this which gave encouraging results[4] But the method is of little use, for if the toe is strapped quite straight the patient cannot wear his shoes—not because the strapping is too bulky but because his shoes are not designed to accommodate his foot with the hallux straight

Operation cases—It is useless to attempt to cure by operation without removing

[4] Pratt C A [illegible] of Chiropody [illegible] 1949

A remarkable feature of this necrosis, and one that contrasts strongly with the fatty liver, is the suddenness with which it develops. Nevertheless, as F. W. Hoffbauer (University of Minnesota) showed, it is possible to abort the acute attack by testing the urine daily for bilirubin, and giving protective substances as soon as bile appears. In this way recurrent non-fatal episodes can be produced. In the livers of these rats Hoffbauer found the pathological picture first described by Himsworth and Glynn—a coarse, so-called post-necrotic, scarring, which cannot be regarded as a true cirrhosis. It was agreed in the discussion that this lesion in the rat is a good counterpart of the Marchand type of coarsely nodular cirrhosis in man. However, H. Popper (Chicago) pointed out that a pure Marchand's cirrhosis, in which the surviving tissue between the scars is normal, is rare in human pathology. Usually the remaining tissue shows a diffuse fibrosis, perhaps caused by damage to the vascular tree.

A puzzling characteristic of dietary liver necrosis is that it can be prevented by two apparently unrelated substances—cystine or sulphur-amino-acids, and vitamin E. The rôle of tocopherol was first discovered by K. Schwarz (National Institutes of Health, Bethesda); his work was done in Germany during the war, and was not known at the time in England or America. In these countries attention had been concentrated on deficiency of sulphur-amino-acids as the causative factor. Great variability was found, however, in the incidence of the lesion in different laboratories—a variability that was explained when Gyorgy independently discovered the part played by vitamin E and the need for controlling its level in the necrogenic diet. These difficulties have now been overcome, and M. Goettsch (University of Puerto Rico) described how the lesion can be produced with extreme regularity if the mother is depleted of vitamin E during pregnancy and lactation, being given only just enough to prevent resorption of the fœtus. G. Klatskin (Yale University) reported that in cirrhosis in man there is evidence that the tissues are depleted of tocopherol.

Disturbance of metabolism of sulphur-containing substances was mentioned by several speakers. H. Popper (Chicago) described the lesions produced in rats by the anti-metabolite ethionine, and by bromobenzene, which acts as a drain on sulphur reserves because it is detoxicated by combination with cysteine. Neither of these poisons produce massive necrosis; the former causes fatty liver, the latter zonal degeneration. J. M. R. Beveridge (Queen's University, Kingston, Ontario) reported that thyroidectomy protects against dietary necrosis; this may be because it increases the number of available sulphydryl groups in the tissues. Finally, in experiments on enzyme activity R. E. Olson (University of Pittsburgh) showed that though—surprisingly—zymes are well preserved in the necrotic liver, there is decreased concentration of the sulphur-containing oenzyme A.

Obscure though the picture is, it is further complicated by Schwarz's discovery that there is a third protective substance, present in commercial casein and in some strains of yeast. This has provisionally been called 'factor 3.' Its identity has not yet been elucidated, although over 800 different fractions have been tested on some 10,000 rats. These figures illustrate the immense scale of the work that has to be done in the isolation and biological testing of a new protective factor.

Conclusion

The conference demonstrated the advantage of such n exchange between clinical and experimental workers. t should not be assumed that only the clinicians gained; or it seems clear that in this field medicine retains its rôle as a spur to the biological sciences.

In England Now

A Running Commentary by Peripatetic Correspondents

I do not set myself up as the discoverer of the ubiquity of the guilt feelings in the anxiety neuroses, but now I come to think of it I certainly did come upon it independently of its original discoverer.

It was this way. About thirty years ago I was in practice in a small village where I was the parish doctor. Like all parish doctors I was sorely troubled by the usual little clutch of neurotics who, entitled to free treatment, saw no reason for putting any bounds to their demands. Every day and all day the wearisome squad laid siege to my consulting-room. The chief of my tormentors was a long-faced spinster of forty, who for the wind in her stomach had drunk deep of every bottle on my shelves, to whose back I had applied every species of plaster, and even—my most powerful charm—on the nape of whose neck I had stuck the most avid and bloodthirsty of my leeches. All to no avail; I cured one pain only to arouse ten others in its place. At last when my bottles were dry, my leeches gorged, and my purse empty I turned upon her. With anger in my voice I broke in on the thousandth variation on her theme of aches and pains with: "What wickedness have you committed that the Lord should afflict you in this way?" And then I stopped. with qualms of conscience. Surely I had gone too far, and she would turn on me with the outraged innocence of a vestal virgin accused of a miscarriage. But no. she was silenced . . . for the first time in many years. Embarrassed and confused she gathered her things together, and mumbling something almost inaudible about being no worse than a lot of people she could name but wouldn't, she went away. And what is more she stayed away, avoiding me as one who had read her guilty secret and whom she had better not annoy.

Well there it is. With my little one-and-only discovery I shall pass with my betters into the limbo of the forgotten. I cannot even dream of my name figuring in a little italic footnote in some authoritative textbook of the future: "A similar observation was made independently twenty years later by Smithers of Great Squelching."

* * *

I was taking advantage of the premature spring to mow the lawn. My two nieces. Christine, aged six, and Gabrielle, aged four, were both working on their own vegetable patch. I heard a shout, and looked up to see Gabrielle running towards me holding her forehead from which trickled a thin stream of blood.

"Hallo, nipper, what's happened?"

"Christine hit me with her spade."

I strode over to Christine and said: "Christine, did you hit Gabrielle with your spade?"

She went on turning the earth and said "No."

"Christine, tell me the truth, did you hit Gabrielle with your spade?"

She picked up a worm and threw it away and, without turning round, said: "No."

By this time I was pretty hypertensive. "Christine," I thundered, "I will give you one more chance. DID YOU HIT GABRIELLE WITH YOUR SPADE?"

The tears were spurting out of her eyes as she turned the earth. "No. It was *her* spade."

* * *

The Hasheaters (*Homo sapiens* var. *caledoniæ*), who were oddly ignored by Dean Swift, live in the North of Scotland, and are distinguished by two principal characteristics; the habit, whence their name derives, of mixing soup, joint, and pudding together in a basin and eating the result with a large wooden spoon; and a propensity for reckless rock-climbing.

I first became aware of their existence on a shimmering summer's day last year; I was sunning myself in a safe corner in the Grampians, when the silence was disturbed by a rich, if untrained, baritone voice singing *When I'm cleaning windows.* I trained my glasses on the corrie whence the sound came, and saw a party of three climbers about half-way up an exposed buttress some 500 feet high. I had just noted that the leader was wearing a bright blue jersey, when to my horror he fell a matter the œsophagus and I did a gastrectomy below the ulcer, the only time I have used the device, the patient has not bled since, and is well two years later I have no use for total gastrectomy for a non-malignant lesion

London, W 1 HENEAGE OGILVIE

A DESIGN FOR FAMILY PRACTICE

SIR,—In my article of March 21 I had no intention of involving the College of General Practitioners in medical politics, with which as Dr Hunt (March 28) points out, it is not concerned

Four years' experience of good working conditions in general practice have shown me that the family practitioner is discouraged from making full use of such conditions because of the basic economic factors operating in the National Health Service In my view, this is the biggest obstacle to the realisation of the ideals of the new college Whether or not it is removed altogether is of course a matter for the General Medical Services Committee

Burley near Ringwood ROBERT HOWARD

MENTAL HEALTH RESEARCH FUND

SIR —The Mental Health Research Fund was founded in July, 1949, and last year you were good enough to draw attention to it in a leading article and by your report of the inaugural conference at Oxford[1] Many of your readers will have seen, in the *Times* of March 10, a letter making the fund known to the public and inviting contributions In launching this public campaign it seems appropriate to recall our purposes and hopes to the minds of doctors

That research in mental health is needed is abundantly clear from the high incidence of mental illness in the community and from the growing population of our mental hospitals Fortunately research methods are full of promise and yearly become more accurate and delicate We hope the fund will be able to offer grants to approved research projects, and wish to remind your readers that its outlook is catholic as we stated in the *Times*, it is not wedded to any particular approach to this many-sided subject The governing body is composed mainly of people who are already active in fields bearing on the mind, and the fund works in close touch with the National Association for Mental Health

If as we hope, there are those among your readers who would wish to give this fund their support, we are in a position to assure them that any contributions which they can secure for the fund would be used to good advantage We shall be glad to send further particulars of the fund to any doctors or laymen who may be interested

INFLUENCE OF LANGUAGE ON MEDICINE

SIR —Prof J Z Young (March 28) quotes the motto of the Royal Society (*nullius in verba*) and states that it seems to suggest that we ought to try "to escape from the persuasive effect of language on our observations and instruments" But the motto is an abbreviation of a line in which Horace describes himself as *nullius addictus iurare in verba magistri* (not bound over to swear allegiance to any master)

That "Don't be a slave to words" is good counsel no one will deny but here we have a far more important injunction don't be a slave to anyone's ideas even if he is "the best authority", ask what his evidence is

Nullius in verba is surely the finest motto a scientific society could have Can any of your readers say who adopted it for the Royal Society ?

London W 1 JOHN PRYNN

Public Health

The Salford Survey

THE survey of the population of Salford by mass radiography is the largest study of its kind yet undertaken in the United Kingdom The six mass-radiography units of the Manchester Regional Hospital Board are to operate in Salford for at least six months, with the object of examining as many as possible of those who live or work in the city The target is set at 100 000 volunteers, but it is hoped that this number will be greatly exceeded It is expected that a considerable number (perhaps up to 200) new cases of pulmonary tuberculosis as well as of other chest abnormalities of significance will be discovered In order that patients suffering from infective tuberculosis shall receive hospital treatment as quickly as possible, additional tuberculosis beds have been made available at the Ladywell Hospital Salford, and elsewhere

Apart from the removal of coats and jackets, undressing before examination has been dispensed with and open public sessions have been arranged at which anyone may attend without appointment For those unable to attend at the open sessions, appointments will be made for convenient days and times, including evenings Special arrangements have been made for the examination of school children All householders will receive a personal letter from Dr J L Burn the medical officer of health, inviting their cooperation and explaining the aims and the scope, and relevant details of the survey All the larger employers of labour in the city have been invited to participate and certain periods have been set aside for units to operate in industrial premises Details of the survey have been notified to all trade unions and the large majority have already promised their aid Other publicity will be given through posters pamphlets, bookmarks short advertising films, slides, and newspaper advertisements The British Broadcasting Corporation has promised to cover the survey in its news service, while religious leaders and all the secretaries of local organisations, such as the W V S the Boy Scouts organisations and old people's clubs have been invited to help

Units are housed in vans 27 ft long, weighing approximately 11 tons Five units are allotted to five main areas of the city, while the sixth which operates indoors on mains electricity supply, will be used for examining special groups—including patients referred by family doctors, expectant mothers, hospital staffs, and inmates of old people's homes and Darby and Joan clubs Besides the use of mass radiography, special tuberculin surveys will be made, particularly in children under 5 years of age A start has already been made in children's Homes and Corporation Nurseries

In a recent statistical survey it was found that of twenty large county boroughs in England and Wales Salford had the second highest death-rate from respiratory tuberculosis, and a random sample of at least 1% of the population will be studied in an endeavour to isolate the social, occupational, and epidemiological factors responsible for infection

Medical and administrative working parties have been set up The former, which deals with the medical, clinical and social approach to the problem, includes Dr Norman Kletz (chairman) Prof Fraser Brockington Prof Wilfrid Gaisford Prof Ronald E Lane Dr Burn and Miss Nancy Goodman with Dr F C S Bradbury, Dr William Lee Dr M Greenberg Dr J S B Mackay, Dr Ronald Walshaw Dr Randal Staller, and Dr J O Fegan

Examination of the general public will begin next Monday

Smallpox

A further 5 cases of smallpox have been confirmed in the outbreak in Lancashire and the West Riding, bringing the total to 21 by April 7 There have been 2 more deaths making 4 in all a 19 year old youth died on April 1 and a 44-year old Todmorden woman on April 3 on the skin adjacent to each side of the nose and on the nasolabial folds. The middle of the forehead and chin were involved to a lesser degree. This red phase, which was attended by intense burning sensations, continued for about 2 days and then subsided, being replaced by desquamation. By about the 7th day the active disturbance seemed to cease, but within a day or two the prodromal prickling would return and the cycle of events was repeated. The patient's mental state, especially during the prodromal and red stages, was one of extreme nervous irritability with alternating moods of depression in which her only wish was to withdraw. These psychological features may have been at least in part a response to the painful discomfort and the disfigurement, but this is not necessarily the complete explanation.

---

[1] *Lancet* 1952 i 681

The patient was examined by several dermatologists who thought the condition might be a neurodermatitis. A variety of applications were suggested and tried but none proved beneficial. X-ray treatment was also given but this seemed to aggravate. She was also seen by a physician, who carried out a series of tests for allergy; but these revealed nothing definite. She was then referred for psychological investigation, but no association could be determined between "the disease" and any disturbing emotional events. The patient herself began to study the reactions to various articles of diet, with negative results except that the attacks seemed to be less severe, and even occasionally to abort, when she used bread made by a certain baker, which, in those days of war (1943–44), seemed to be definitely lighter in colour than the standard loaves of the times. In pursuit of this possible clue I wrote to my friend, the late Sir Jack Drummond, who caused inquiries to be made. He reported that there was no difference in the flour used in the lighter-coloured bread from that particular baker and the loaves made by others. I replied that this seemed odd, inasmuch as the colour of this bread was as distinct from the loaves of other bakers as the two shirts in the advertisement for 'Persil.' In any case this lighter-coloured bread soon after ceased to be obtainable and the dermatitis resumed its relentless course.

In 1945 the eruption, for some reason or other, began to subside; at any rate it was much less troublesome. But it returned abruptly in October, 1946, and the state of the patient again became desperately unhappy. Remembering the 1943 experience of the apparently whiter loaf, we decided to try the effect of excluding from the diet all products containing flour. The effect was immediate and dramatic. The exclusion began at a time when the cycle was just entering its red phase. This subsided at once, desquamation was minimal, and further eczematous manifestations ceased. From then on the patient used potatoes and home-made oatcakes in place of breadstuffs. From time to time an experimental addition of small quantities of bread was made to the diet but only minute amounts could be tolerated. I approached the Ministry of Food on behalf of the patient and provided them with an account of the occurrence. They generously secured for her, in return for the surrender of her bread coupons, a supply of imported white flour which differed (but in what chemical aspects I do not know) from the high-extraction flour in general use in Britain at the time. This supplement to her diet enabled the patient to maintain weight and keep the dermatitis in abeyance. If, however, at any time she was on holiday and partook of the usual breadstuffs the dermatitis reappeared. In the course of the following years she came to acquire a certain and increasing tolerance to limited amounts of breadstuffs, but even to this day great care has to be exercised.

Other points of interest are that during the illness the patient was found to be extremely susceptible to nicotinic acid. Also, after a second injection of penicillin a fortnight after a first, the skin responded by the not unusual german measles type of reaction, and at a later date a small plug of penicillin inserted into a socket after a tooth had been extracted produced an alarming dermatitis of the hands which looked like crocodile skin and were exceedingly swollen, stiff, and painful for several weeks. I wondered if the sensitisation to the allergen in flour had in some way facilitated an increased sensitivity to other allergens.

The point that impressed me most was the *dramatic* nature of the response. Seldom have I seen such a clear-cut instance of immediate "cause" followed by immediate "effect." Much, of course, remains to be understood. There is no information as to the frequency of such occurrences; no information about the "kind of person" who responds to flour in this way: no real understanding of the bodily mechanisms involved. All that can be said at this stage is that in respect of at least two cases of obscure and distressing eczema it has become a little clearer as to why they took ill when they did and recovered when they did. Yet because of the dramatic nature of the response, both to the provocation and its withdrawal, a vista of investigations opens out—as, for instance, into the various disorders which have definitely or seemingly increased during the last twenty or thirty years. For example, if one took a series of patients with active duodenal ulcer and treated every second case with complete withdrawal of modern flour under its various guises, one would soon secure an answer to what part, if any, was likely to be played in its ætiology by at least one of our common foodstuffs.

Glasgow S.1. J. L. HALLIDAY.

VISITS TO CHILDREN IN HOSPITAL

SIR,—Professor Moir, whose remarks at a meeting of the Leeds Regional Hospital Board were reported on March 28 (p. 656), is a busy consulting surgeon who probably has not the time to observe children in hospitals where daily visiting is allowed and to compare them with children whose parents are excluded from the ward. The evidence of those who have had the time to make such observations shows that his belief that children forget their parents if they are left alone for a day or two lacks any basis in fact.

It is doubtful if the professors of child health in the Universities of London, Sheffield, and Newcastle, to name but a few, are swayed by "sloppy sentiment" in their condemnation of the old practice of depriving sick children of parental love. Let Professor Moir read the evidence in Dr. John Bowlby's *Maternal Care and Mental Health* [1] or see the Tavistock Clinic's film, *A Two Year Old goes to Hospital*,[2] and he will soon realise that sound sense and realism underlie the humane changes that many pædiatricians are eager to bring about.

Newcastle upon Tyne J. G. NEVILLE.

VITAMIN E AND INTERMITTENT CLAUDICATION

SIR,—Dr. Loxton (March 28) criticises us for trying to prove a null hypothesis (that vitamin E has no more effect on intermittent claudication than an inert substance); and he asserts that this null hypothesis has, in fact, already been disproved by other workers. We cannot accept as *disproof* the results of trials, however extensive, which have not been adequately controlled, and we have already emphasised that previously reported results fall into this category. Had the efficacy of vitamin E been previously established by an adequately controlled series, our trial would have been unnecessary.

We completely agree, of course, that the null hypothesis cannot be *proved*, and we are sorry if the condensation required in the summary of our paper, and in our subsequent letter, has led Dr. Loxton to think otherwise. Indeed, we were careful to state in our article (Feb. 21, p. 369):

> "The rather small numbers of patients available in this trial may have led to moderate effects of vitamin-E treatment not being detected owing to the considerable variability between patients."

And we proceeded, in table VIII, to give confidence limits for the mean effect of vitamin-E treatment in comparison with the controls. We found, for example, that it is most unlikely that vitamin E increases the average exercise tolerance after the treatment period by as much as 2·3 circuits, or about 12%, since the mean exercise tolerance is about 19 circuits.

Although a null hypothesis can never be *proved*, it must often be right to act as though it were true when

might mutilate the National Health Service? Everybody knows that he is the avowed enemy of the service, as he has publicly declared, and in his own hands it has already received many grievous blows The best service he could render it would be to resign

Mr **MACLEOD** It is true that this matter has been considered at the highest levels of Government, but we consider—and it is possible to disagree on this—that it is essentially a departmental matter and therefore, that this announcement should be made by myself and not by the Chancellor of the Exchequer as part of the Budget speech This is a long-term problem which in the view of most people remains essentially unsolved

When the right hon gentleman suggests that we should remit this question to the Central Health Services Council—or that we should take account of their views on this kind of matter—I entirely disagree It is because the council are representative of wide interests within the health service that I do not consider them to be the proper body for an inquiry of this nature In my view, what is needed is an entirely independent inquiry It should not in any sense be a political one nor one which is linked in any way, through the membership of the committee, to any of the professions concerned in the health service

With regard to the accusations that the right hon gentleman was good enough to end his speech with in the first place I should not have agreed to a committee—nor would Mr Guillebaud have accepted the chairmanship of a committee—which was designed to mutilate the National Health Service

Mr **BEVAN** May I call the Minister's attention to the first error that he made in the course of his statement? I never suggested that these terms of reference should be sent to the Central Health Services Council I suggested that they might be asked for their advice about any organisational modifications Is an expenditure equal to £100 million in the National Budget, and which concerns the welfare of all the citizens of Great Britain, a fit subject to be remitted to a committee of inquiry? If so, why does not the Chancellor of the Exchequer remit to a committee of inquiry the question whether taxes should be lower or higher Why does not the Chancellor of the Exchequer hand his Budget to a committee of inquiry?

Mr **RICHARD FORT** Many inside this House and outside will welcome the statement and the opportunity to have a large amount of information about costs and expenditure brought together in a form in which we can really appreciate its value In putting this matter before the committee, will he ask their opinion about the effect of making block grants to the hospitals, which would give regional boards greater independence?

Mr **MACLEOD** Block grants come within the terms of reference That is a subject on which people hold strong views and on which there may conceivably be considerable saving I have no doubt that the points of view for and against block grants will be put to the committee

Mr **ARTHUR WOODBURN** May I ask the Minister whether he is aware that a reading of the terms of reference creates the impression that they are tendentious and that they are suggesting to the committee what the committee should report? Since an economist is being put in charge of the committee, is it its purpose to find out as the Organisation and Methods Department of the Treasury might find out, whether the existing service can be more economically worked? Is the Minister aware that there is a Select Committee of this House which inquires into these matters and which may have been examining this question already? Has he considered that this may be a reflection upon them? If this committee is to give a balanced report to the House will it be called upon to find out what was the cost of preventable disease in this country before the health service was introduced? If my memory is correct, before the war the Minister's Department estimated it at £550 million a year May I ask him whether he will broaden the terms of reference so that if the committee is to report on the economics of the health service it will report on them comprehensively as they affect the whole country?

Mr **MACLEOD** I do not agree with the right hon gentleman in his reading of the terms of reference This is a general inquiry into the function, structure, a[nd] policy of the service and not an economy-cuts committee It is true that the Select Committee have done admirable work in this field but that touches only the fringe of the very much bigger problem Many countries have made experiments in social welfare and we ourselves have had this splendid experiment going on now for five years But not everybody is satisfied that we and other countries have found the ideal way of running the service and the ideal way of financing it We can honestly differ about this, but in my view a committee not tied to any profession in the health service or to any political party is the best way in which we can seek answers to these difficult questions This is a very long-term business It will take many months and perhaps a year

Later in an adjournment debate on a personal case in which it was alleged that N H S hospital authorities offered a patient insufficient help on a long railway journey, Mr. **ARTHUR BLENKINSOP** asked whether there could be any connection between a case of this kind and the drive for the general reduction of expenditure in the National Health Service There must be a good deal of misunderstanding about the cost of our health service, he continued It seemed to be evident that the Minister was accepting without question as a fact that it was costing far more than was necessary, and that great economies could be carried out without danger to the service and to the treatment provided for patients within it He was anxious as to whether this drive for economy might not cause countless more cases of this kind He could not emphasise too strongly that, far from the over-all expenditure on the health service being too great we must examine the point as to whether or not extra additional expenditure was urgently required for the benefit of the community He agreed that economies could still be made in the health service but there were fields in which large sums of new expenditure were required Over these last few years owing to the imposition of an over-all ceiling upon health expenditure, at the same time as costs had been rising the services given within the service had had to fall As this became more severe, especially this year, the pressure upon every hospital authority to deal with rather less than its customary good will with individual cases was bound to grow Because the costs of the service were rising, including food costs, the hospitals like other sections of the service were having to face all the time the need to cut down what they could provide and this at a time when in our interests as a community we should expand many of the services that richly needed expansion What was more, there was a lot of loose talk as though the total sums that we spent upon our health service were in some way astronomical and quite beyond our ability to pay Was that really true? No one had attempted to examine our total costs today as against the total costs of health care in the days before the health service was introduced Certainly, we spent a much smaller percentage of our national income on health care than was done in America In his view hospitals were not being given sufficient funds to enable them to maintain properly the fabric of their buildings As the years went by and if not enough money was put into the work, we would be faced with enormous costs There were great jobs of work that needed to be done that in the interests of economy ought to be carried out If the present procedure was carried on, if we maintained this artificial ceiling that had been running for some four years he ended we were in effect denying to the health service the finances that it must have if it was to devel[op] properly

QUESTION TIME

Drugs, Dressings, and Appliances for Private Patients

Sir **EDWARD KEELING** asked the Minister of Health how much it would cost the taxpayer to give drugs dressings and appliances to private doctors' patients after deducting the 1s prescription charge, but without allowing for the transfer of many National Health Service patients to private doctors which would follow such gift —Miss M P **HORSBRUGH** replied If the net cost per person were the same as for persons under the National Health Service (which assumes the private doctors would be bound to observe the same conditions as National Health Service doctors) the total cost to the taxpayer might be nearly £1½ million per annum secure value for money. The introduction of unnecessary high-priced polypharmaceutical mixtures encourages waste of public money, and must bring forward the day when practitioners are allowed to prescribe only from a standard formulary and manufacturers will have to secure a licence to use a proprietary name for their preparations. The introduction of such mixtures is against the best interests of the medical profession and of the pharmaceutical industry.

Central Middlesex Hospital,
London, N.W.10. GEORGE DISCOMBE.

POLIOMYELITIS

SIR,—I was surprised to see that Dr. Ritchie Russell and several of your correspondents state that a pillow or a board at the foot end of the bed are sufficient to prevent drop-foot. This may look satisfactory enough when a patient has been neatly arranged for an official ward round; at all other times we find that the feet are simply not up against the support. Unless a child is very severely paralysed it will move about in bed a little, and its position is in any case frequently disturbed for bed-making, toilet, &c. We find that club-foot shoes are necessary to prevent equinus deformity.

This brings me to another point. We have several children in this hospital in whom muscle spasm has persisted for more than a year after their acute illness; at least this is how it appears to us. In most cases the calf muscles are affected but in one patient it is the biceps. The affected muscles can be stretched to their full extent by firm, sustained pressure, so we are not dealing with a true contracture. If left unsplinted the limb takes up a position of pronounced deformity. The stretching causes a good deal of pain, and this is worse when the patient fails to coöperate. If he can be taught to relax there is less difficulty in stretching the muscle, and once fully stretched it seems to become painless. In some of these cases the opponents of the painful muscles are completely paralysed, in others they have a fair power of contraction; the exact strength is difficult to assess under the circumstances.

I would be most interested to hear views on the true nature of this condition and its prevention. Should passive stretching be performed more vigorously and earlier? At present we do little in the first three weeks; after that patients are treated once daily. I might add that the patients thus affected are not necessarily those that have been rigidly splinted. In fact, as far as we can see, rather the reverse is the case, and the patient with the spastic biceps was certainly never splinted at all.

King Edward VII
Orthopædic Hospital, Sheffield. E. G. HERZOG.

POLIOMYELITIS IN DENMARK

SIR,—Although Dr. Anderson and his colleagues (March 28) object vigorously to my letter of March 14, it is, I think, obvious that both they and I are advocating the same need to enlist assistance to maintain a free airway in patients suffering from acute poliomyelitis with bulbar and/or respiratory paralysis.

They favour strongly Dr. Lassen's method of tracheotomy with positive-pressure breathing, whereas I would urge that this is not the best way to keep these patients alive. In the 50 paralytic patients dealt with from this department at Stoke Mandeville Hospital during 1952, all survived (except one infant aged 2 weeks) without any having a tracheotomy; and at least 6 of these cases would have qualified for the Copenhagen treatment.

We were probably lucky, but we also had a most careful nursing drill for maintaining the airways clear. The vital importance of frequent changes of posture (every 2 hours) was emphasised in this recent experience by the fact that, though none of the patients developed atelectasis while under special nursing care, 2 with severe intercostal paralysis developed atelectasis when this care was relaxed 3–4 weeks after the onset of the illness. The longest period of complete paralysis of swallowing was 2 weeks. Removal of secretions with a sucker is a traumatic procedure, and we were glad to find that the sucker is rarely required when postural drainage is efficiently maintained. In this connection Dr. Anderson and his colleagues scoff at my emphasis on the prone posture, but in this they betray a common failure to understand that postural drainage of the lungs can only be effective for anatomical reasons if the prone posture is used freely. Tank respirators must be so designed that the patient can lie prone; and both of the latest respirators, now manufactured respectively by Messrs. Siebe, Gorman Ltd. and Messrs. Stanley Cox Ltd., fulfil this requirement satisfactorily. The cuirass respirator fails in this respect, and in any case does not give sufficient tidal air for acute cases.

It is gratifying that the Copenhagen experience has made it so very apparent that saving life in the acute stage depends on preventing atelectasis, but the uncritical advocacy of the Danish emergency measures as the method of choice is surely somewhat unwise. Their mortality-rate for cases of bulbar and/or respiratory paralysis (about 40%) can, I believe, be improved upon by other well-tried and safer methods.

Department of Neurology,
Radcliffe Infirmary, Oxford. W. RITCHIE RUSSELL.

OSTEOPATHY

SIR,—In the discussion of this subject by correspondents, one vital point seems to have been overlooked. The positioning of the vertebræ depends primarily on muscle action. Muscle action, in the absence of an obvious lesion, is primarily a behavioural manifestation which involves the whole organism. No amount of "re-positioning of the vertebræ" either by gentle or by forcible manipulation will get around the fact that when a person is accustomed to using his body in a certain way, he will return to this way after the manipulation. It is no help to give specific exercises to "maintain the osteopathic correction": it is the total behaviour pattern which usually needs re-educating, not the individual muscles.[1]

This is not to deny that manipulation may on occasions dramatically remove symptoms of pressure; but a predisposition to set up a faulty vertebral alignment will remain until the total behaviour pattern has been re-educated.

London, S.W.7. WILFRED BARLOW.

SIR,—Spinal-nerve-root compression, it seems, may be due to a displaced fragment of the annulus of an intervertebral disc (Dr. Cyriax, March 21) or to narrowing of the intervertebral distance, with sometimes pressure on the radix from the displaced disc, or from its extruded nucleus pulposus (Dr. Turner, March 28). For the practical purpose of treating the condition, it is unimportant which explanation one accepts, for the result does not depend on a particular pathological theory.

The Cyriax manœuvres can be successful: Dr. Turner admits this, but insists with understandable prejudice that osteopathic methods are better. He who advises manipulative treatment for this condition, however, has often to choose between an osteopath (who may or may not have the same training and use the same method as Dr. Turner, who may in fact have received his diploma from a correspondence school, or who may have had no training at all) and a physiotherapist of the St. Thomas's school, all of whom use the Cyriax technique. The latter will often be the safer choice.

It seems pointless to argue the merits of the rival schools: both methods have their successes, and the will consider, among other things, the effect of noise in relation to human efficiency The harmful effects of noise on the individual can be reduced to some extent by the wearing of protective ear coverings and by eliminating injurious noise at its source by improved designs of machines and their mountings and the sound insulation of walls and ceilings, but the subject has been found to bristle with practical difficulties

---

[1] Barlow, W. *Ann. phys. Med.* 1952, 1, 77.

Dr STROSS Is the Minister aware that protective ear coverings appear to be very much in their infancy and that there is not a satisfactory type available? Could he tell me if scientific research is to be conducted into finding the right type of protective ear covering for these men? Mr WATKINSON Yes, that is so

Obituary

CECIL HOLMES LYON

O B E, F C I I

THE death of Mr C H Lyon, clerk of the London Executive Council on March 22 while still in office, brings a sense of loss to very many London doctors He joined the service of the London Insurance Committee in 1913, becoming its registrar at the end of the first world war In 1932 he was promoted to be deputy clerk, and he succeeded Mr Gilbert as clerk of the infant London Executive Council in 1919 So highly were his services valued that when his retiring age approached, his council unanimously asked him to continue his work

J A S writes "Lyon's efficiency and quiet friendliness were always at the disposal of individuals as well as of the professional bodies whose work was linked with his council At the meetings of the London Medical and Dental Committees and their subcommittees his interventions were rare but his advice, leavened always with a quiet humour, was always welcome and often sought The same unobtrusive friendliness marked his dealings with doctors who sought his guidance on the problems of practice in the National Health Service His warm humanity was fortified by his Masonic activities and by his interest in Hayes Parish Church, where he was for many years organist and choirmaster"

Notes and News

ASSOCIATION OF CLINICAL BIOCHEMISTS

THE inaugural meeting of the Association of Clinical Biochemists was held at the Postgraduate Medical School of London on March 28 The formation of the association springs from a meeting in May, 1952, at which representatives of societies of clinical biochemists in Glasgow, the Midlands and north western and southern England set up an interim committee under the chairmanship of Prof F J [illegible] The association will be both scientific and professional in scope On the professional side it will concern itself with the status of qualified biochemists working in hospital and allied laboratories who have not hitherto been specifically provided for by professional associations In the scientific sphere it will work in the rapidly expanding field of clinical biochemistry, where pathology, clinical medicine, and biochemistry overlap, and which is not systematically covered by any of these branches of science The association will hold regional and national meetings at which papers will be read and demonstrations given Joint meetings with other societies will be arranged both locally and nationally The association hopes also to cooperate with the member societies of the International Association of Clinical Biochemists in a scheme for standardising and periodically checking analytical methods used in hospital laboratories

The inaugural meeting accepted a set of rules submitted by the interim committee, who are to hold elections not later than Aug 31 The association will be directed by a president and a council composed of chairman, secretary, treasurer and two nationally and five regionally elected members The interim committee is acting as a provisional council with Dr A L Tarnoky (Royal Berkshire Hospital, Reading) as secretary

The following papers were read at the inaugural meeting E B Love (Preston), laboratory control of anticoagulant therapy, I D P Wootton (London), quartz spectrophotometer in clinical chemistry; H Bickel, J Gerrard, and E [illegible] Hickmans (Birmingham) influence of phenylalanine intake on phenylpyruvic oligophrenia, and A L Latner (Newcastle upon Tyne), quantitative paper strip electrophoresis of serum proteins

HEALTH REGULATIONS FOR WORKERS

THE International Labour Organisation has reported a division of opinion among governments in regard to a set of proposed international regulations to safeguard the health of workers in their places of employment The proposed regulations constitute one of the eight items on the agenda of the I L O 's general conference that opens at Geneva on June [illegible]

The question was first discussed by the general conference last year,[1] when it was agreed that this year's conference should pursue it further on the basis of a report to be prepared by the I L O after consultations with governments It was also decided that the 1953 conference should determine whether the proposed regulations should take the form of (1) a recommendation or (2) one or more conventions supplemented by a recommendation

The I L O report, lately published, proposes two alternative sets of texts for consideration by the conference One of these is a proposed recommendation, the other comprises two proposed conventions supplemented by a recommendation One of these conventions would regulate the medical examination of workers and the other would require the notification of cases of occupational disease The proposed recommendation deals with the technical measures for the control of health hazards, medical examinations, and the notification of occupational diseases The proposed supplementary recommendation which deals with the same subjects, is intended to serve as a guide to governments in the event of the conference deciding on the adoption of conventions supplemented by a recommendation The suggested provisions for medical examinations are restricted to workers in occupations involving special risks to health The notification of occupational disease would, in principle, apply to cases and suspected cases, and the competent authority in each country would be left to draw up a list of notifiable diseases

The report discloses that 24 governments have no general comment to make and that they consider the proposed texts suitable for discussion by the conference Nine governments favour the adoption of a recommendation alone T secure value for money. The introduction of unnecessary high-priced polypharmaceutical mixtures encourages waste of public money, and must bring forward the day when practitioners are allowed to prescribe only from a standard formulary and manufacturers will have to secure a licence to use a proprietary name for their preparations. The introduction of such mixtures is against the best interests of the medical profession and of the pharmaceutical industry.

POLIOMYELITIS

SIR,—I was surprised to see that Dr. Ritchie Russell and several of your correspondents state that a pillow or a board at the foot end of the bed are sufficient to prevent drop-foot. This may look satisfactory enough when a patient has been neatly arranged for an official ward round; at all other times we find that the feet are simply not up against the support. Unless a child is very severely paralysed it will move about in bed a little, and its position is in any case frequently disturbed for bed-making, toilet, &c. We find that club-foot shoes are necessary to prevent equinus deformity.

This brings me to another point. We have several children in this hospital in whom muscle spasm has persisted for more than a year after their acute illness; at least this is how it appears to us. In most cases the calf muscles are affected but in one patient it is the biceps. The affected muscles can be stretched to their full extent by firm, sustained pressure, so we are not dealing with a true contracture. If left unsplinted the limb takes up a position of pronounced deformity. The stretching causes a good deal of pain, and this is worse when the patient fails to coöperate. If he can be taught to relax there is less difficulty in stretching the muscle, and once fully stretched it seems to become painless. In some of these cases the opponents of the painful muscles are completely paralysed, in others they have a fair power of contraction; the exact strength is difficult to assess under the circumstances.

I would be most interested to hear views on the true nature of this condition and its prevention. Should passive stretching be performed more vigorously and earlier? At present we do little in the first three weeks; after that patients are treated once daily. I might add that the patients thus affected are not necessarily those that have been rigidly splinted. In fact, as far as we can see, rather the reverse is the case, and the patient with the spastic biceps was certainly never splinted at all.

King Edward VII
Orthopædic Hospital, Sheffield. E. G. HERZOG.

POLIOMYELITIS IN DENMARK

SIR,—Although Dr. Anderson and his colleagues (March 28) object vigorously to my letter of March 14, it is, I think, obvious that both they and I are advocating the same need to enlist assistance to maintain a free airway in patients suffering from acute poliomyelitis with bulbar and/or respiratory paralysis.

They favour strongly Dr. Lassen's method of tracheotomy with positive-pressure breathing, whereas I would urge that this is not the best way to keep these patients alive. In the 50 paralytic patients dealt with from this department at Stoke Mandeville Hospital during 1952, all survived (except one infant aged 2 weeks) without any having a tracheotomy; and at least 6 of these cases would have qualified for the Copenhagen treatment.

We were probably lucky, but we also had a most careful nursing drill for maintaining the airways clear. The vital importance of frequent changes of posture (every 2 hours) was emphasised in this recent experience by the fact that, though none of the patients developed atelectasis while under special nursing care, 2 with severe intercostal paralysis developed atelectasis when this care was relaxed 3–4 weeks after the onset of the illness. The longest period of complete paralysis of swallowing was 2 weeks. Removal of secretions with a sucker is a traumatic procedure, and we were glad to find that the sucker is rarely required when postural drainage is efficiently maintained. In this connection Dr. Anderson and his colleagues scoff at my emphasis on the prone posture, but in this they betray a common failure to understand that postural drainage of the lungs can only be effective for anatomical reasons if the prone posture is used freely. Tank respirators must be so designed that the patient can lie prone; and both of the latest respirators, now manufactured respectively by Messrs. Siebe, Gorman Ltd. and Messrs. Stanley Cox Ltd., fulfil this requirement satisfactorily. The cuirass respirator fails in this respect, and in any case does not give sufficient tidal air for acute cases.

It is gratifying that the Copenhagen experience has made it so very apparent that saving life in the acute stage depends on preventing atelectasis, but the uncritical advocacy of the Danish emergency measures as the method of choice is surely somewhat unwise. Their mortality-rate for cases of bulbar and/or respiratory paralysis (about 40%) can, I believe, be improved upon by other well-tried and safer methods.

Department of Neurology,
Radcliffe Infirmary, Oxford. W. RITCHIE RUSSELL.

OSTEOPATHY

SIR,—In the discussion of this subject by correspondents, one vital point seems to have been overlooked. The positioning of the vertebræ depends primarily on muscle action. Muscle action, in the absence of an obvious lesion, is primarily a behavioural manifestation which involves the whole organism. No amount of "re-positioning of the vertebræ" either by gentle or by forcible manipulation will get around the fact that when a person is accustomed to using his body in a certain way, he will return to this way after the manipulation. It is no help to give specific exercises to "maintain the osteopathic correction": it is the total behaviour pattern which usually needs re-educating, not the individual muscles.[1]

This is not to deny that manipulation may on occasions dramatically remove symptoms of pressure: but a predisposition to set up a faulty vertebral alignment will remain until the total behaviour pattern has been re-educated.

London, S.W.7. WILFRED BARLOW.

SIR,—Spinal-nerve-root compression, it seems, may be due to a displaced fragment of the annulus of an intervertebral disc (Dr. Cyriax, March 21) or to narrowing of the intervertebral distance, with sometimes pressure on the radix from the displaced disc, or from its extruded nucleus pulposus (Dr. Turner, March 28). For the practical purpose of treating the condition, it is unimportant which explanation one accepts, for the result does not depend on a particular pathological theory.

The Cyriax manœuvres can be successful: Dr. Turner admits this, but insists with understandable prejudice that osteopathic methods are better. He who advises manipulative treatment for this condition, however, has often to choose between an osteopath (who may or may not have the same training and use the same method as Dr. Turner, who may in fact have received his diploma from a correspondence school, or who may have had no training at all) and a physiotherapist of the St. Thomas's school, all of whom use the Cyriax technique. The latter will often be the safer choice.

It seems pointless to argue the merits of the rival schools: both methods have their successes, and the

Nursing Fellowship

The University of Edinburgh has appointed Miss G B Carter, B SC, S C M, S R N, to the Boots Research Fellowship in nursing, tenable in the department of social medicine

Dental Service

On March 26 the Minister of Health, the Minister of Education, and the Under Secretary of State for Scotland received a deputation from the British Dental Association, the purpose of which was to discuss the difficulties of the school dental service.

Naval Medical Compassionate Fund

A meeting of the subscribers will be held at 3 P M on Monday, May 4, at the Medical Department of the Navy, Queen Anne's Mansions, St James's Park, London, S W 1, to elect six directors of this fund

Exhibition of Medical Photography

An exhibition entitled 100 Years of Medical Photography is to be held at the Royal Photographic Society, 16, Princes Gate, London, S W 7, from April 7 to 30 (Mondays to Fridays 9 30 A M to 5 30 P M, Saturdays 9 30 A M to 5 P M)

Medical Award

Dr Dorothy Meiklejohn has been appointed M B E *in* recognition of her bravery when Mau Mau terrorists attacked her and her husband in Kenya last November Her husband later died from his injuries

Mental After Care Association

The annual meeting of this association will be held at the apartments of the Royal Society, Burlington House, Piccadilly, London, W 1, on Friday, April 17, at 3 P M when the speakers will include Dr Henry Yellowlees, chairman of the association

W H O Conference on Health Education

Between April 10 and 18 the World Health Organisation is holding in London a regional conference on health education, which is being attended by experts from the United Kingdom and eighteen countries of Western Europe The joint chairmen are Prof J M Mackintosh and Dr Aujaleu (France)

Laboratory Animals Bureau Congress

The sixth Laboratory Animals Bureau Congress, held at the Royal Veterinary College London on March 27 and 28, was attended by some 250 technicians The congress was opened by Sir Harold Himsworth secretary of the Medical Research Council The proceedings will be published in the *Journal of the Animal Technicians Association*

Conference on the Family

The second British National Conference on Social Work, organised by the National Council of Social Service, is to have as its theme The Family The meetings, which will start at 9 30 A M on Thursday, April 16, and continue for three days, are to be held at Bedford College for Women, Regent's Park, London, N W 1 Medical speakers will include Dr John Bowlby and Dr Rene Sand (Belgium)

Anniversary of Harvey's Birth

A commemoration of the 375th anniversary of Harvey's birth held in his native town of Folkestone on April 1 (*Times*, April 2, p 5) was attended by the Mayor of Folkestone and Dr T Hare president of the Harveian Association The Rev J V Hooper, Vicar of Hempstead where Harvey is buried, announced that last year's ceremony had brought such public support to the fund of his church that the Harvey tomb and chapel were now almost restored

CORRIGENDUM *Rothschild Hadassah University Hospital, Jerusalem*—In our advertisement columns (March 28, p 35) applications were invited for the posts of head of the E N T department and head of the ophthalmological department at this hospital The salary for a full time appointment in each case is I£270 (pounds Israeli) per month, plus family allowance A corrected notice appears in this issue

EMERGENCY BED SERVICE.—In the week ended last Monday applications for general acute cases numbered 1043 The proportion admitted was 91 2%

Dr C J Austin is shortly to retire from the post of medical superintendent of the Fiji Leprosy Hospital at Makogai which he has held for nearly twenty two years

the cause. This is the reason for the failures of surgical treatment—not bad surgery, not bad luck, but failure to remove the cause. The straightened toe is immediately deformed again when the patient wears shoes.

With the patient standing upright with the feet close together, the normal, or restored to normal, feet make contact with each other throughout their length. There is no angle or gap between the big toes. Only shoes that have a straight inner border and no gap between the inner side of the toes can therefore accommodate the feet in this shape (fig. 2).

Which is the most effective operation for advanced hallux valgus I am not competent to say. I suggest, however, that the best method will only be effective if the patient wears correctly designed footwear after the operation.

Prevention by Correct Footwear

I do not myself wear correctly designed shoes, for I do not know where I can buy them, and I cannot afford to have them specially made. Some children's shoes are correctly designed but most are not.

Through my Member of Parliament, I have asked the Minister of Health to create a Seal of Approval which manufacturers under licence could emboss on their footwear to show that it is correctly designed—the first requirement of design being that the footwear must accommodate the straight hallux. The Minister seems to favour the idea of a seal but he is unwilling or unable to do anything about it himself. In my view it is the duty of a Minister of Health to take immediate action to reduce the crippling prevalence of hallux valgus.

The first requirement is official medical approval of a correct design; and this would form the basis of whatever further action is necessary. Surely the medical profession is prepared to tell the shoe manufacturers what are the medical requirements for satisfactory footwear? Only when this has been clearly stated can we expect manufacturers to comply with these standards; and upon their action successful treatment and prevention depend.

Neither apathy nor opposition should delay action, for only when we have revolutionised the design of footwear can we confidently recommend an operation for advanced hallux valgus and look forward to the day when hallux valgus will be of interest only to the historian.

London, S.E.22. **CHARLES A. PRATT.**

MENTAL ACTIVITY IN INFANCY

SIR,—Mrs. Collis (March 28) misses the point of our argument. We agree that "mental and motor defects both affect physical activity, though in differing ways." We cannot, however, agree that the tests recommended by Mrs. Collis can be relied upon to separate mental deficiency in cerebral palsy from mental retardation due to the motor defect. We argued that all the tests for mental development were motor tests only. The term "release phenomena" as applied to tonic neck and tonic labyrinthine reflexes is, we believe, common neurological usage. We used this term as it seemed to us relevant to the problem for at least two reasons. First, the degree of release is a direct indicator of the severity of the motor handicap. Secondly, the released motor phenomena, by their persistence and strength, are responsible for the non-appearance of a higher integrated motor behaviour that may well be, and often is, potentially present.

London, W.1.

KAREL BOBATH
BERTA BOBATH.

SIR,—Professor Illingworth agrees, in his letter last week, that it is through its physical expressions that we judge mental development. As he himself admits, however, assessment of this through alertness, interest (or awareness), social responsiveness, response to sound, grasping reactions, and vocalisations (all mentioned in my original text) relies upon the infant's neuromuscular coördination. At the time when this "is not quite ready" for mature expression, and in cases where it is impaired, assessment by these means is impracticable. It was for these reasons that I ventured to select some other neuromuscular reactions of infants and to suggest that their modification may also be linked with mental advance.

Cerebral Palsy Unit,
Queen Mary's Hospital for Children,
Carshalton, Surrey.

EIRENE COLLIS.

THE PROBLEM OF PEPTIC ULCERATION

SIR,—I must agree with most of Mr. Downie's criticisms last week of my "annual lecture." I can only plead that it was the best I could do under the circumstances—an hour in which to cover a large topic before a mixed audience, few of whom were surgeons. I have, however, a few comments on each of his paragraphs.

Mr. Downie seems to have found some political or social implications in my views on the ætiology of ulcer. I can assure him none were intended. Certainly most of my ulcer patients are both intelligent and ambitious, but they are all "just ordinary chaps," and quite a few of them are bus drivers. I find out if a bus driver is ambitious by talking to him as a man rather than a patient, by discussing with him his job, his home, his family, and his pals as well as his pain. I am not sure that the word "stress" is really a "meaningless phrase"; I prefer it to the "adaptation syndrome" which has the semblance of meaning without the reality. The struggle for existence is not new, but the constant awareness of the struggle is a phenomenon of the present century, as is duodenal ulcer.

With the views on the indications for operation that Mr. Downie expresses in his second paragraph I feel less happy. He says: "I hope Sir Heneage will agree that in the treatment of peptic ulcer there must be one law for the rich and another for the poor." I could not agree less. I feel very sorry for the German who lost his motorcycle because he had a month of medical treatment for his duodenal ulcer, but the implication that he might have kept it had he been admitted to the surgical wards seems to err on the side of optimism. The figure "40" has no more magic than 400 or 0·4; but merely represents my opinion which, on this occasion, I had been asked to give. We must all operate earlier sometimes. I have recently been forced to do a gastrectomy on a boy of 14. But, in my view, we should remember that gastrectomy, successful as it is, is a gross mutilation, a wholesale sacrifice of normal tissues and of one of the most important phases of normal digestion. The man who has lost the major part of his stomach has lost most of his reservoir, most of his mechanical kneading apparatus, most of his mechanism for dealing with meat-fibres, and most of his protection against swallowed bacteria. How sure are we that a man so deprived will not eventually suffer some hormonal or nutritional disturbance? We know already that he appears to suffer no ill effect in twenty years. Have we any right to assume that this immunity will hold good for forty or sixty years?

I did not discuss the treatment of high gastric ulcers, because I was not speaking to those who were interested in technical details. In any case my experience is nothing to that of Norman Tanner. I agree, however, that the high gastric ulcers, particularly that group that Mr. Downie has recently discussed so ably,[1] the high lesser-curve ulcers that cannot be demonstrated by X rays or the gastroscope but that bleed *torrentially*, present a problem of real difficulty. I personally have only found one in which it was not possible to do a high Billroth-I gastrectomy of the Pauchet type, cutting round the ulcer with scissors. In one the ulcer involved passive antibody which will prevent paralysis and that inhibiting alimentary infection Bodian (1952b) states that a level which is barely detectable in neutralisation tests can protect cynomolgus monkeys from paralysis, whereas titres five hundred times as great still permit alimentary infection in the chimpanzee In the cynomolgus monkey specific serum antibody can prevent paralysis after alimentary infection (Bodian 1952c)

---

[1] Downie, V. J. *Brit. med. J.* 1952, ii, 24.

It should be mentioned here that, though in these experiments the borderline titre appeared to be about 0 01 ml gamma-globulin per kg, Wood et al (1952) have shown that in man only very small amounts of Lansing antibody appear in the serum after the inoculation of gamma-globulin in doses of 0 1–0 4 ml per lb body weight The two series of experiments are not strictly comparable, because Wood used larger amounts of virus in the neutralisation tests than did Bodian

On the basis of his findings, and those of other workers whose reports did not at the time fit in with current theory, *Bodian suggests a reconsideration of the pathogenesis of poliomyelitis* He postulates that there are three phases of virus growth—alimentary, vascular, and neural His hypothesis is that the vascular phase, responsible for high antibody titres, may be initiated by penetration of the virus from the alimentary tract into the blood stream or the regional lymph glands The virus then enters the central nervous system via the bloodstream—possibly, on the basis of histological findings, by the area postrema in the floor of the fourth ventricle

ACTIVE IMMUNISATION OF MAN

Koprowski et al (1952) fed a monkey-adapted Lansing type strain to 20 volunteers, who were then studied clinically, serologically, and by the examination of stools for the presence of virus In no case was any illness observed in the volunteers

At the beginning of the experiments the sera of 3 volunteers contained neutralising antibodies and 2 others gave equivocal results, 12 of the remaining 15 excreted virus after feeding, and in all 15 a high titre of neutralising antibodies was then found In 12 cases the process was repeated, and in 2 of them alimentary reinfection was achieved The remainder neither excreted virus nor showed any change in antibody titre In 1 of these 2 cases a third feeding yet again produced alimentary infection, but a fourth attempt gave negative results in both On the second feeding their antibody levels were similar to those of the remaining 10, but a further increase in antibody took place in 1 In the other, whose stools were negative after a third feeding, an increase in antibody was nevertheless then detected In 2 of the 3 volunteers whose sera showed significant antibody levels at the beginning of the experiments a carrier state was again established, but none of them showed any further increase in antibody at any time No search was made for virus in the blood stream of any of these volunteers

PASSIVE IMMUNISATION OF CHILDREN

Almost 55 000 children were inoculated with either gamma globulin or a control gelatin solution during September, 1951 and July, 1952, in four epidemic areas of the United States (Hammon et al 1952) The dosage of gamma globulin was high, averaging 0 14 ml per lb body-weight The children were carefully followed up particularly from ten to thirty days after inoculation By October, 1952 90 children who had been followed for at least thirty days were considered to have contracted paralytic poliomyelitis Of these, 26 had gamma globulin and 64 gelatin—a statistically significant difference

In 28 cases which occurred during the first week after inoculation 12 children had received gamma globulin and 16 gelatin During the second week, however there were 3 cases in the gamma-globulin group and 23 in the controls and this striking difference persisted until the fifth week From the second to the fifth week there were 6 cases in children who had received gamma globulin and 38 in children who had received gelatin—a highly significant difference After the fifth week the difference between the two groups was slight

Up to now the only results available are those based on clinical grounds, and no laboratory examinations have been reported Hammon et al suggest that the gamma globulin should not have interfered with inapparent infection and development of active immunity This is, of course, the crux of the problem, and, should there be no such interference, there may well be a field of usefulness for this method

Lymphoid Tissue and Blood

There is considerable evidence that poliomyelitis affects lymphoid tissue No time relationship has yet been established but, obviously, studies of regional lymph glands during the incubation period of the experimental disease might be rewarding Sommers et al (1951) have pointed out that in the paralytic disease the most consistent and most severe lesions of any outside the central nervous system are in lymphoid tissue Wenner and Paul (1947) and Wenner and Rabe *(1951) have isolated the virus from lymph glands* at necropsy I would enter a plea for more critical study of the ileum Sabin and Ward (1941) and Wenner and Paul (1947) have isolated the virus from its wall, and it does seem that in this region the anatomical requirements both for growth and antibody production are all present

Direct evidence that poliomyelitis virus is to be found in the blood stream of man is meagre Two isolations have already been mentioned, and 13 cases of poliomyelitis in the first fortnight of life have been recorded (Baskin et al 1950, Wright and Owen 1952) There is also evidence of *myocarditis in the early stages of* infection (Laake 1951)

In spite of this lack, there is so much suggestive indirect evidence that in discussing Bodian's hypothesis it seems legitimate to go further and to adduce evidence from other virus diseases In some of these it has been found that the virus travels from the site of entry to the regional lymph-glands where it multiplies This is followed by invasion of the blood stream, by which other lymphoid tissues, including probably the spleen, are infected After a further period of growth here there is a secondary viræmia, during which the virus travels to those cells which, when attacked, give the clinical picture of the disease This sequence can be modified by existing antibody or the administration of gamma globulin

Spread of Virus

The first question that arises is the function of circulating antibody in poliomyelitis, and it is now accepted that in laboratory animals immunity runs parallel with the titre of neutralising antibody One can reasonably suggest that in man also the function of antibody is the provision of *immunity* Howe (1951) has pointed out that alimentary infection appears to be the essential part of natural immunisation For the regular production of antibody in any quantity it seems that the virus must appear in the blood stream If it does, is it there as part of the disease pattern or as an *incidental leak* from the intestine? Proof of its presence in the blood is lacking but we have not even begun to study the incubation period in man

It is tempting to think that, when we do study it we may find a picture similar to that outlined, in which entering through the nasopharynx or alimentary tract after local and then generalised growth in lymphoid tissues the virus travels in the blood stream to settle in cells of the gastro intestinal tract In some cases the virus may also enter the central nervous system and in some of these it may cause paralysis whether this is a function of the virus or of the host we do not know This hypothesis of generalised spread may be supported

The 5 new cases are all in the direct line of contact with earlier cases; 4 of these patients live in Halifax and 1 in Oldham. So far there have been 11 confirmed cases in Todmorden, 2 in Bacup, 2 in Oldham, 2 in Bury, and 1 in Halifax.

Tuberculosis in Scotland

The report for 1952 of the Department of Health for Scotland [1] describes the decline in tuberculosis mortality which we referred to last week (p. 702). The reduction in the death-rate from respiratory tuberculosis was shared by all the age-groups of both sexes, with the exception of males at the extremes of life. In 1952 there were 1404 deaths—a rate of 27 per 100,000. Among young women aged 20–24—a particularly susceptible group—the death-rate fell from 122 per 100,000 in 1950 to 45 per 100,000 in 1952. These improvements were "due to improved medical and surgical treatment, together with the fact that the disease is now being brought under treatment at a much less advanced stage." Notifications of tuberculosis in Scotland were also fewer: the provisional total for 1952 was 7259, compared with 7776 in 1951. In the last quarter of the year, however, the number of notifications showed very little change from the corresponding figure for 1951. The report says that the number of hospital beds for patients suffering from respiratory tuberculosis rose from 5967 at the end of 1951 to 6098 a year later. During the same period the waiting-list fell from 3129 to 1711. By the end of 1952, 412 patients had gone to Switzerland under the Swiss-Sanatorium Scheme.

The South Eastern Regional Hospital Board has been operating a scheme for seconding student nurses from the general training-schools in Edinburgh for a period of work in tuberculosis wards; and this scheme has enabled additional beds to be opened during 1952. The arrangement has proved successful and has been welcomed by the nurses themselves. A similar scheme is starting in Aberdeen. So far it has not been possible to do the same in the western region, where the need is greatest, but, the report remarks, "it is hoped that fuller co-operation from the main training hospitals will shortly be forthcoming."

Colour-vision of School-children

In his report for 1952, Dr. J. F. Warin, school medical officer for Oxford, describes the results of colour-vision tests performed on children between 10 and 11 years of age. During the past four years 4973 Oxford children have been examined, and 67 of them, all boys, were found to have some degree of colour-blindness. The majority of those affected had a slight red-green defect. The prevalence of colour-blindness among the boys tested was approximately 2·6%.

De-salting Brackish Water

Under the auspices of O.E.E.C. a working party was set up last year to study the de-salting of brackish water. De-salting concerns many countries where water-supplies are short or are likely to become so, including the Netherlands, South Africa, the West Indies, and Pakistan.

The working party appointed a group of experts to study four processes which were thought to merit further investigation. These are ion-exchange, separation by freezing, electrolysis, and vapour compression distillation. The group is now drawing up its report. Later the working party should be able to recommend one or more processes for coöperative development to countries of O.E.E.C., including the United Kingdom. These countries will be free to collaborate or not, as they choose.

The idea of a working party on de-salting came originally from the Netherlands, where the underground water level is falling and the water getting brackish. Although de-salting is not yet a serious problem in Britain there is a tendency for certain London supplies to become slightly brackish.

Those interested in the progress of the work on this subject should apply for further information to the Department of Scientific and Industrial Research, Charles House, 5, Regent Street, London, S.W.1.

Dangerous Drugs Regulations

The Dangerous Drugs Regulations, 1953,[1] which came into force on March 31, consolidate and amend the earlier regulations. They apply to all substances to which the Dangerous Drugs Act, 1951, applies, with the exception of certain drugs listed in a schedule to the new regulations. The main amendments include a provision for midwives to possess and administer medicinal opium, tincture of opium, and pethidine procured upon an order signed by the medical officer of health, or a person authorised by him, up to the amount specified in the order. Hitherto a midwife was required to produce her personal register of cases to the chemist supplying the drugs. A relaxation order,[2] which also came into force on March 31, recognises that morpholinylethylmorphine is now of medical value by freeing it from the restrictions on sale and manufacture imposed by the Dangerous Drugs Act, 1951, on certain alkaloids and their derivatives which are not used for medical or scientific purposes.

Parliament

Review of Cost of N.H.S.

On April 1 at the end of question time Mr. Iain Macleod, the Minister of Health, announced the appointment of a committee to review the cost of the National Health Service.

The Secretary of State for Scotland and I, Mr. Macleod said, have had under close review the whole problem of the present and future cost of maintaining a proper and adequate National Health Service, and we have already initiated a number of administrative and other measures designed to alleviate the considerable cost to the taxpayer without impairing the quality of the service provided. But these are, inevitably, measures of detail and the general long-term problem remains essentially unsolved.

After a great deal of thought, the Secretary of State and I both feel that the many issues involved in this problem are so complex that the wisest course will be to refer the whole matter for an independent and objective inquiry by a committee. We therefore propose to appoint a small committee with the following terms of reference:

> "To review the present and prospective cost of the National Health Service; to suggest means, whether by modifications in organisation or otherwise, of ensuring the most effective control and efficient use of such Exchequer funds as may be made available; to advise how, in view of the burdens on the Exchequer, a rising charge upon it can be avoided, while providing for the maintenance of an adequate Service; and to make recommendations."

Mr. C. W. Guillebaud, the Cambridge economist, has accepted our invitation to be chairman of the new committee. I will inform the House as soon as possible of the names of the other members.

Mr. Aneurin Bevan: May I ask whether the Cabinet, as a whole, seriously decided that this was an issue that should be remitted to a committee of inquiry. Is it not in fact a matter primarily for the House of Commons, for political decision, and is it not an act of the most unprecedented political cowardice to send to a committee a matter which is at the centre of British politics? Not only modifications to the organisation are to be discussed but, in the words of the terms of reference, "or otherwise." In other words, the whole central question whether there should be any longer a free health service in Great Britain is to be remitted to a committee of inquiry. If the Minister is going to have advice upon the question whether any modifications in the organisation of the health service ought to be made, why does he not ask for the views of the Central Health Services Council, which is exactly suited to that purpose, and which is a repository of expert knowledge on this subject? Is it not a fact that what he is doing, as a consequence of struggles between himself and the Treasury, is seeking another instrument by which he

papilloma $^1/_4$ in in diameter, on the upper part of the anterior wall The patient looked and felt well and had no symptoms I can recall only two of the many cystoscopic occasions when the bladder was free from papilloma

Case 2 —A woman, aged 67, has been treated by me for twenty four years by cystoscopic diathermy for vesical papilloma and is keeping very well, though when last examined, on Oct 24, 1952, there was still a patch of sessile papilloma on the left side of the bladder base

Although these two cases had several features in common, they differed in the following respects in case 1 the recurrences were widespread and sometimes pedunculated, and they rapidly reappeared , in case 2 the reappearances were *consistently at the left side* of the bladder base, were never pedunculated, and did not recur rapidly

It is a point of interest that I cannot recall any female case of vesical papilloma that became malignant after many years of cystoscopic fulguration On the other hand malignant disease has appeared in three of my male patients treated for simple growths by cystoscopic fulguration over periods of thirteen, fourteen, and twenty three years The danger is always there Nor *does a long lapse of time give complete security against* a reappearance of a simple growth, which may afterwards become malignant

I have the records of a case whose treatment was concluded by a late and able colleague, and who came to me twenty eight years later with a quite small papilloma—an obviously recent recurrence He was last seen by me with a further recurrence simple in appearance, thirty one years after the original discovery

Once a bladder has been rendered free from growth by cystoscopic diathermy, the intervals at which subsequent inspections are made will vary from case to case, according to how often recurrences are found But all these cases should be inspected at least once a year indefinitely

CYSTOSCOPY

Cystoscopic appearances of carcinoma should present no difficulty to the expert eye In fact, it is essential that the cystoscopist train himself to recognise the characters of malignancy

The following are the signs which have guided me to this diagnosis

(1) Ulceration of the growth surface

(2) The presence of a firm smooth nodule of growth or of a firm bulge of the vesical mucosa in the vicinity of the growth The firmness is estimated by probing with a diathermy electrode

(3) Hyperæmia of adjacent vesical mucosa This obliterates the outlines of individual blood vessels and is generally widespread

(4) Œdema of or surrounding, the new formation This sometimes results in bullæ

(5) A firm base to a sessile proliferation when probed with a diathermy electrode

(6) A lack of progress from treatment by several well conducted cystoscopic diathermy applications

(7) *A precipitate edge to a necrotic area of the proliferation* This is the only cystoscopic sign which has enabled me to distinguish between simple and non invasive malignant papilloma

Calculous deposit adherent to a necrotic area of growth must be considered with circumspection and a necrotic surface—short of ulceration—of a papilloma will also create a doubt , but in either case one or two vigorous diathermy treatments, followed by careful cystoscopy should settle the question

Suspicious appearances must be thoroughly investigated by a second cystoscopy after a suitable interval following a vigorous diathermy Inspection within about two weeks of diathermy application may reveal surrounding œdema which is entirely attributable to the treatment

A new case of bladder growth presenting with persisting dysuria or increased frequency, as well as hæmaturia which is not terminal, probably is a case of carcinoma , and the patient should be admitted to hospital for the first cystoscopy, so that, if fulguration is necessary to aid the diagnosis, it may be given on this occasion This is important because a quickly repeated cystoscopy in such a case may find the bladder so irritable as a result of the first examination that a satisfactory opinion must be delayed

BIOPSY

It is my practice not to rely on a cystoscopic biopsy As I have already emphasised, it is only the exceptional case of infiltrating carcinoma that cannot be recognised at once cystoscopically When one is able to make such a definite decision, it is certainly a waste of valuable time to delay further action until a laboratory report comes to hand Moreover where the report is negative one may still doubt whether the right piece of tissue has been removed

Even in a difficult case which has required a delayed inspection following a fulguration the uncertainty is generally cleared up at the second cystoscopy Where the diagnosis in such circumstances is still doubtful, or positive, I prepare to open the bladder on a subsequent early occasion to apply radium treatment, at the same time taking the biopsy specimen In fact, as will be shown later, an excellent result may be expected from implanting radium into a non-infiltrating papilloma

It sometimes happens that, by following the above rules of treatment, a biopsy report of tissue taken on the occasion of the opening of the bladder to implant radium shows that the case is one which might well have been left to cystoscopic diathermy treatment That is a hazard which the above routine always holds but which becomes reduced to a negligible size as the experience of the surgeon increases

Three of my early cases fell into this category, and it is of great interest to me to be able to record their after history They had the common features of single sessile papillomatous growths, 1–1$^1/_2$ in in diameter, they were treated with radium , and the patients were alive and well seventeen, fourteen and eight years afterwards One tumour was of non invasive anaplastic malignancy the second was reported to be non malignant , and in the third no biopsy was made In the eight year case the patient died at the age of 83 without signs of recurrence or metastasis, and in the fourteen year and seventeen-year cases both patients are still alive and well at the ages of 74 and 77

I have two reasons for reporting these cases (1) the bladders of all 3 patients remained free from post radium irritation , and (2) there was no reappearance later of even a simple papilloma I believe the explanation of the *latter fact to be that radium implanted into* a non invasive malignant or a simple papilloma where there has not yet been more than one mass of growth present, allays the tendency towards further reappearances of papillomata

This is in striking contrast with the course of events in two other separate groups of papilloma of the bladder

1 Radium implanted into a single papilloma of low malignancy when simple papillomata are present elsewhere in the bladder

2 Either single or multiple papillomata treated by diathermy only

In both these groups there is a tendency towards recurrence

The way in which, in the less malignant growths, the use of radium inhibits reappearance elsewhere in the bladder has been emphasised by Frankson (1950) It may well be that we are approaching an era when some simple form of radiation will be a regular part of the treatment of simple papilloma

TOTAL CYSTECTOMY OR RADIUM ?

Both cystectomy and radium have had a fair trial and it is now possible to compare the results Those of

Hospital Salary Awards

Replying to a question, Mr. Iain Macleod stated that the estimated cost in 1953–54 of wage and salary awards made to all full and part time hospital staff during the last 12 months was approximately £6¼ million.

Training of Oral Hygienists

Mr. Blenkinsop asked the Minister why he had decided to close the training-school for oral hygienists early in 1954.—Miss Hornsby-Smith replied: The school was organised solely for the purpose of an experiment, now completed, in the training and use of oral hygienists and was financed wholly from public funds. The final report on the results of the experiment was published in the annual report of the Central Health Services Council for 1951.

Control of Cortisone

Replying to a question, Mr. Peter Thorneycroft, president of the Board of Trade, said licences permitting private commercial imports of finished cortisone were not at present being issued. Supplies were purchased by the Ministry of Health for continuing clinical research and for use in selected hospitals where treatment could be strictly supervised.

Mr. Bence: It is not much use giving people this excellent treatment in hospital if it is to be discontinued as soon as they leave hospital.—Mr. Thorneycroft: I understand that the Ministry of Health still consider it necessary to control the use of this drug very carefully as the knowledge of its long-term effects is so far incomplete. In the view of the Ministry adequate supervision of treatment can only be ensured if the treatment is carried out in this way for the present.

Capital Expenditure on Mental Hospitals

Replying to a question, Mr Macleod, the Minister of Health, stated that the estimated capital expenditure on mental hospitals and mental deficiency institutions during 1948–49, 1949–50, 1950–51, and 1951–52 was respectively 13, 17, 15, and 21% of the total capital expenditure on hospitals.

University Grants

Replying to a question, Mr. J. A. Boyd-Carpenter, financial secretary to the Treasury, said that the total of recurrent grants to universities and university colleges in Great Britain for the academic year 1952–53 was £20 million. Of this sum, Oxford University would receive £1,215,000, Cambridge University £1,325,000, and London University £6,280,000. In addition, non-recurrent grants were made in response to specific applications. Non-recurrent grants paid in the academic year 1951–52 amounted to £7,002,095, of which Oxford University received £311,191, Cambridge University £297,005, and London University £1,821,221.

Coalminers and Pneumoconiosis

In answer to a question, Mr. L. W. Joynson-Hicks, arliamentary secretary to the Ministry of Fuel and Power, aid that about 80 coalminers in 1950, and 101 and 112 in the wo following years, were advised to leave the industry, or suspended, on account of having pneumoconiosis with tuberculosis.

Sick Pay in Government Departments

In answer to a question, Mr. Boyd-Carpenter stated that a report by the Medical Research Council revealed no evidence that there was any serious abuse of sick-pay schemes in Government industrial departments, but departments were continuing to watch sick-absence rates carefully to determine whether any modifications appear desirable.

Post-war Loaf

In answer to a question, Major Gwilym Lloyd George gave the following details of the investigations made on the points raised in paragraph 65 of the report of the Conference on the Post-War Loaf (Cmd. 6701).

The nutritional value of the “reinforced” flour which is available in the United States is not strictly comparable with that of the “restored” flour which will be available in this country. There is, however, no evidence that the “token” nutrients added in the processes of either “reinforcement” or “restoration” differ from those naturally present in the wheat grain. Investigations have shown that no means are available to determine with certainty whether the “token” nutrients in flour are of natural origin or have been added.

The policy of the Government is to allow complete freedom to the milling industry to produce flours of any level of extraction for any purpose, subject to the restoration of the “token” nutrients to all flours below 80% extraction. This question does not therefore arise. Flour of 80% extraction (which will be used among other purposes for the National loaf) will automatically contain the required levels of token nutrients, and in these circumstances producers of National flour will need no safeguard beyond that which they can themselves provide by milling to 80% extraction. Flour milled at lower rates of extraction will have to be fortified by the addition of the quantities of token nutrients required to restore the level to the minima recommended by the Conference on the Post-War Loaf.

A review has been made of wheat varieties from the point of view of their “token” nutrient content as well as their milling and baking qualities, but no useful action appears to be practicable. The question in this subparagraph does not arise as there will be no restriction on the rate of extraction of flour imported into the United Kingdom.

British Hertford Hospital, Paris

Replying to a question, Mr. H. A. Nutting, under-secretary for foreign affairs, said that no decision had yet been taken by the committee of the hospital on the hospital's future; but it was likely that it would have to be closed unless it could continue to be maintained either from local income or from donations from this country towards its running expenses.

Fluorine Gas Contamination

Dr. Barnett Stross asked the parliamentary secretary to the Ministry of Works, as representing the Lord President of the Council, what research was being made into the problem of fluorine gas contamination of the atmosphere, resulting from the firing of sanitary and other ware in continuous kilns; and whether he would make a statement on the effects of the inhalation of this gas by human beings.—Mr. A. H. E. Molson replied: In 1947 the British Pottery Research Association, which is now part of the British Ceramic Research Association, completed a thorough investigation of this problem. Their recommendations for the avoidance of the nuisance were agreed to and published by the Chief Inspector of Alkali Works in his report for that year. Fluorine gas does not occur free in Nature and when given off in an industrial process quickly combines with the moisture in the air to form hydrogen fluoride. If hydrogen fluoride is present in sufficient concentration it causes irritation of the eyes and respiratory system. I am advised that no record can be found of cases of hydrogen fluoride poisoning in this country.

Tuberculosis in Glasgow

Replying to a question, Commander T. D. Galbraith said that in 1952 the death-rate from respiratory tuberculosis was 49 per 100,000 population for Glasgow, and 22 for the rest of Scotland excluding Glasgow.

Replying to a further question. he added that at the end of 1952 there were in the Western Region 3303 staffed beds for respiratory tuberculosis. More beds could have been brought into use had there been nurses available to staff them. The waiting-list for sanatorium treatment in the region at Feb. 28 was 1230. Half this number of additional beds would enable the waiting-list to be cleared quite quickly.

Spastic Children in Scotland

In an answer to a question, Mr. J. Henderson Stewart stated that there is 1 residential school in Scotland which provides exclusively for spastic children, the Westerlea School of Spastics, Edinburgh. In addition there are 5 residential schools for physically handicapped pupils which take some spastic children. There is no hospital unit set aside solely for spastic children. Those who need hospital care are dealt with in local general hospitals or in orthopædic units in larger central hospitals. Educational facilities are available to children who have to stay long in hospital.

Deafness Caused by Industrial Noise

Dr. Barnett Stross asked the Minister of Labour whethe he had noted that about half the number of men employe in chipping, riveting, stamping, plating, and heading becam deafened to speech at more than three feet after 20 yea exposure to the noise created at their work; and what ste were being taken to protect them from this type of deafne —Mr. Harold Watkinson replied: My Department is aw of the recent report of a committee of the Medical Rese Council on the medical and surgical problems of deaf and that exposure over many years to noise above cer intensities may cause deterioration in hearing. Much rese is being carried out into this question. and a committe been set up jointly by the Department of Scientific Industrial Research and the Medical Research Council

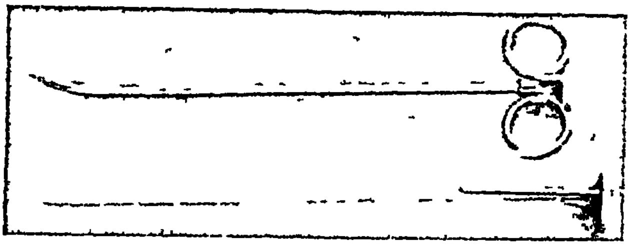

Fig 3—Radon seed introducer with guide-pin on handle

For accurate placing I do not withdraw the inserted instrument until the next one is placed in position In this way proper spacing is not difficult I find it best to work with three introducers, the third holder is necessary to ensure rapid working There is an obvious advantage if the operator can make the insertion with either hand The instrument I use (fig 3) has been made for me by the Endoscopic Company, of London

The considerable amount of intravesical sepsis which follows radium insertion prevents immediate or early closing of the bladder, but with radon the bladder is closed as part of the operation, and the patient is soon about on his feet again This advantage offers an obvious temptation in favour of radon But there is a significant absence of published figures to support any claim that this method can give comparable results to radium in the treatment of infiltrating growths

In this group of cases, after radon has been used, early local recurrence has been my regular experience, and when this happens, the resulting bladder discomfort may call for palliative ureteric transplantation As a contrast with local recurrence after radium, irritation of the bladder is strikingly absent, and the patient at least has a comfortable end

OTHER METHODS

Radioactive wire (tantalum) and fluid are both at present being tried in the bladder, and time is required to show what place these modifications of existing radiation methods will take in the treatment of vesical carcinoma

The practical difficulties of applying X ray therapy to the bladder have so far rendered this method ineffective, except sometimes for controlling hæmorrhage, but there is scope for further efforts

MEASURING THE GROWTH

It has been our custom in this country to have a physicist present in the theatre to estimate the dosage required in relation to the size of the growth When the growth is extensive and occupies an arc of a circle, the dimensions can only be accurately estimated with a malleable measure Callipers are useless I use a piece of lead tape about 8 cm long and graduated in 0 5 cm lengths (fig 4) This, too, was made for me by the Endoscopic Company

SUMMARY

All patients with vesical papillomata should undergo regular cystoscopic inspection indefinitely

Papillomata without cystoscopic features of carcinomata ascertained after careful investigation, should be treated by cystoscopic diathermy

It is generally not possible to distinguish cystoscopically between simple papilloma and non invasive papillary carcinoma

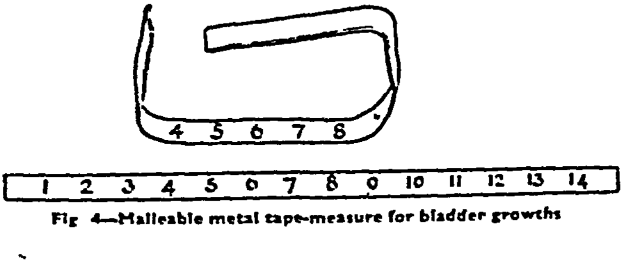

Fig 4—Malleable metal tape-measure for bladder growths

It is essential that a cystoscopist should be able to recognise the early signs of invasive carcinoma

The lack of biopsy details, showing whether the growths in question are infiltrating or not, is a weakness in many statistical reports

It is not possible to assess immediate prognosis merely on a histological grading classification of already infiltrating tumours

Is the growth infiltrating or not ? This is the question of overriding importance in prognosis If the growth is infiltrating, the extent to which it infiltrates is the next most important factor

In trying to balance the claims of one form of treatment against another, it should be borne in mind that the substitution of the large bowel for the urinary bladder generally shortens life

The results of radium treatment are better than those of cystectomy

Evidence is lacking that radon seeds have any more than a palliative action on invasive growths

Metals and fluids rendered radioactive artificially are being used experimentally

SOME DEVELOPMENTS IN THE TECHNIQUE OF TRIGEMINAL INJECTION

JOHN PENMAN
M B Lond, M R C P

NEUROLOGIST, HERTFORD COUNTY HOSPITAL, CLINICAL ASSISTANT, ST GEORGE'S HOSPITAL, LONDON, AND THE MAIDA VALE HOSPITAL FOR NERVOUS DISEASES

THIS paper is a sequel to one about radiological location of the trigeminal needle (Penman 1949) With the exceptions implied below, that technique is unaltered, the approach used is still the anterior, the X ray apparatus is still of the Lysholm Schonander type, the basal and oblique projections are those recommended before, and where Harris's guide lines are mentioned the previous nomenclature will be retained

Choice of Puncture Point

PRE-SELECTION RADIOGRAMS, OR GRID FILMS

Härtel (1912) recognised that the correct puncture point might prove to be anywhere in quite a large area, but stated that the needle should usually enter the cheek opposite the second upper molar tooth This is a difficult instruction to follow in the living, even when the teeth of that region are present, and many patients requiring trigeminal injection are edentulous

Harris (1937) recommended that downwards from the most lateral part of the bony margin of the orbit one should draw a line parallel to the median plane of the face, and take the highest point on that line at which one could conveniently press a finger tip inwards and upwards beneath the lower border of the maxilla The puncture point thus defined is usually at a height about midway between those of the alæ nasi and the angle of the mouth, it is widely used serves extremely well in average cases, and in this paper will be called the conventional puncture point There are two opposite extremes, however, at which it becomes ineffectual Sometimes the anterior surface of the petrous bone is so steep and the foramen ovale faces so much downwards that a needle inserted at the conventional point will either fail to enter the foramen at all or enter it but immediately jam on the petrous bone, or at best lie so close against the petrous bone as to be underneath the trigeminal sensory root Less often the anterior petrous are Australia, Costa Rica, Greece, India, Lebanon, New Zealand, Switzerland, the United Kingdom, and the United States. Six governments—those of France, the Federal Republic of Germany, Israel, Italy, Luxembourg, and Yugoslavia—favour the alternative of two conventions and a supplementary recommendation. Belgium, Egypt, and Sweden prefer a single convention supplemented by a recommendation, while Poland suggests the adoption of three conventions together with a supplementary recommendation.

Conventions adopted by the conference are not binding on a country until ratified but must be considered for possible ratification. Recommendations are not subject to ratification, but countries have the obligation to consider giving effect to them.

APPROVED NAMES FOR DRUGS

The British Pharmacopœia Commission has issued the following new supplementary list of approved names:

Approved name	*Other names*
Benethamine Penicillin ..	N-Benzyl-2-phenylethylamine salt of benzylpenicillin.
Bismuth Glycollylarsanilate	Bismuthyl N-glycollylarsanilate. Milibis.
Cetrimonium Chloride ..	Hexadecyltrimethylammonium chloride.
Hexachlorophane	Di-(3 : 5 : 6-trichloro-2-hydroxyphenyl)methane. Hexachlorophene.
Hyaluronidase	Enzymes which depolymerise hyaluronic acid.
Iodothiouracil	4 - Hydroxy - 5 - *iodo* - 2 -mercaptopyrimidine. Itrumil is the sodium derivative.
Iopanoic Acid	2-(3-Amino-2 : 4 : 6-tri-iodobenzyl)-butanoic acid. Telepaque.
Methylpentynol	3-Methylpent-1-yn-3-ol. Oblivon. Somnesin.
Nitrofurazone	5-Nitrofuran-2-aldehyde semicarbazone. Furacin.
Pentaerythritol Tetranitrate	2 : 2-Bishydroxymethyl-1 : 3-propanediol tetranitrate. Pentaerithrityl Tetranitrate.
Phenylephrine	(−)-1-m-Hydroxyphenyl-2-methylaminoethanol. Neophryn is the hydrochloride. Neosynephrine is the hydrochloride.
Procainamide	4 - Amino - 2 - (diethylaminoethyl) - benzamide.
Procyclidine	1 - *cyclo*Hexyl - 1 - phenyl - 3 - pyrrolidinopropan-1-ol. Kemadrin is the hydrochloride.
Sulphasomidine	6 - p - [illegible]

University of London

Mr. A. d'A. Bellairs, lecturer in anatomy in the University of Cambridge, has been appointed to the readership in anatomy at St. Mary's Hospital Medical School. Dr. K. W. Cross, senior lecturer in human physiology at St. Mary's Hospital Medical School, has been appointed to the readership in human physiology at the school. The title of reader in anatomy has been conferred on Dr. J. T. Aitken in respect of the post held by him at University College.

University of Glasgow

On June 17 the honorary degree of LL.D. will be conferred on Sir Harold Himsworth, secretary of the Medical Research Council.

Royal College of Surgeons of England

The college is to hold a course of surgery lectures and clinical conferences during April. Further particulars may be had from the deputy secretary, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2.

Royal College of Physicians of Ireland

On March 27 the following candidates, having passed the final examination of the Conjoint Board in Ireland, were admitted licentiates in medicine and midwifery:

Jehangir Manek Anklesaria, C. P. Carey, T. H. Chillingworth, J. A. Davies, I. H. C. Lynch, E. A. Moore, Ishverlal Parbhoo, W. V. Reynolds, Denis Ryan, J. F. L. Watson.

Conjoint Board in Ireland

At recent examinations the following were successful:

D.O.M.S.—G. E. C. Hewson.

D.P.M.—S. Lennon, D. E. Munro, E. O. Lundholm, B. G. Fleming, C. McP. Smith, M. A. Rahill, J. W. Sandler, R. A. Robinson, B. A. O'Connell, D. H. A. Irwin.

D.C.H.—G. Bheek, F. P. S. le Roux, Margaret Magill, A. J. MacDonald, A. J. Edwards, E. O'Connor, T. D. Shanahan.

Royal College of Physicians of London

Dr. E. A. Carmichael will deliver the Lumleian lectures at the college, Pall Mall East, S.W.1, on Tuesday and Thursday, April 14 and 16, at 5 P.M. He will speak on Hemiplegia of Early Onset and the Results of Hemispherectomy.

Hunterian Society

The gold medal for 1952 of this society has been awarded to Dr. Douglas French (Kidsgrove, Staffs) and a *proxime accessit* award has been made to Dr. A. E. de la T. Mallett (Wimborne, Dorset). The subject for the 1953 essay is the Management of Peptic Ulceration in General Practice. Further details may be had from the hon. secretary, Mr. Alec W. Badenoch, 110, Harley Street, London, W.1.

Hastings Lecture

Dr. F. A. E. Crew, F.R.S., professor of public health and social medicine in the University of Edinburgh, is to deliver the Hastings lecture at B.M.A. House on Wednesday, May 6, at 6.30 P.M. He is to speak on Medicine and Social Policy. Mr. Walter Elliot, F.R.S., M.P., will be in the chair.

The Hastings lecture of the British Medical Association is intended for the general public, and medical readers are asked to bring this function to the notice of lay people who might be able to attend. Admission is free by ticket obtainable from the Public Relations Department, B.M.A. House, Tavistock Square, London, W.C.1.

Society of Anæsthetists of South Wales

The following officers have been elected: president, Dr. F. Pearson; vice-president, Dr. W. W. Mushin; hon. secretary, Dr. K. S. Thom (41, Caerau Road, Newport, Mon.); and hon. treasurer, Dr. D. S. Jones.

International Congress on Rheology

The second International Congress on Rheology will be held at Oxford from July 26 to 31 under the presidency of Sir Geoffrey Taylor, F.R.S. Further particulars may be had from Mr. G. W. Scott Blair, The University, Reading, Berkshire.

International Congress of Pædiatrics

The seventh International Congress of Pædiatrics will be held from Oct. 12 to 17 in Havana, Cuba. The following subjects have been chosen for discussion: Epilepsy in Infancy and Childhood, Diagnosis of Congenital Malformations of the Heart and Great Vessels Susceptible of Surgical Treatment, Problems of the Premature Infant, Complications of Primary Tuberculosis, and Metabolism and Nutrition Problems. Further particulars may be had from the general secretariat of the International Pædiatric Association, Kinderspital, Zürich, 32, Switzerland.

Opposition to Proposed Sheffield Health Centre

A further attempt to set up a health centre at Firth Park, Sheffield (see *Lancet*, 1952, ii, 346), has ended in failure, according to a report received on April 2 by Sheffield Executive Council of a meeting last month that was attended by Miss E. M. Russell-Smith, an under-secretary to the Ministry of Health. Three doctors, representing their colleagues in the Firth Park area and the Sheffield local medical committee, opposed the project on the ground that coöperative arrangements—partnerships, mutual assistance, and other action to promote group practice—could lead to services equalling those that could be provided by a health centre. The possible loss of freedom and independence by doctors entering a health centre in such matters as the purchase and selection of instruments and equipment was also emphasised. Moreover they would occupy premises as tenants. Other disadvantages included: concentration of a large number of patients in one centre; expense to the taxpayer and ratepayer in providing domestic and secretarial staff, compared with the help now given by many doctors' wives; the unwillingness of patients to attend a centre; and the likelihood of a doctor returning home and finding another set of patients waiting for him. The chairman suggested that the "real and immediate need" was for experimental schemes; but it was pointed out, on behalf of the doctors, that they did not feel the Firth Park district was suitable for an experiment of this kind. Furthermore they did not consider it practicable for a doctor to divide his practice so as to take only a proportion of his patients to the centre. Practitioners in the Firth Park area were unanimous in their opposition to the centre, and it was not possible to say that any of the doctors could agree to work there without incurring the resentment of their colleagues.

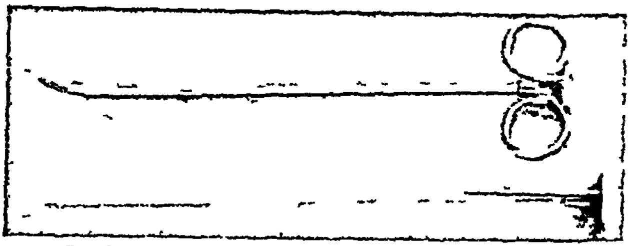

Fig 3—Radon seed introducer with guide-pin on handle

For accurate placing I do not withdraw the inserted instrument until the next one is placed in *position*. In this way proper spacing is not difficult. I find it best to work with three introducers, the third holder is necessary to ensure rapid working. There is an obvious advantage if the operator can make the insertion with either hand. The instrument I use (fig 3) has been made for me by the Endoscopic Company, of London.

The considerable amount of intravesical sepsis which follows radium insertion prevents immediate or early closing of the bladder, but with radon the bladder is closed as part of the operation, and the patient is soon about on his feet again. This advantage offers an obvious temptation in favour of radon. But there is a significant absence of published figures to support any claim that this method can give comparable results to radium in the treatment of infiltrating growths.

In this group of cases, after radon has been used, early local recurrence has been my regular experience, and when this happens, the resulting bladder discomfort may call for palliative ureteric transplantation. As a contrast with local recurrence after radium, irritation of the bladder is strikingly absent, and the patient at least has a comfortable end.

OTHER METHODS

Radioactive wire (tantalum) and fluid are both at present being tried in the bladder, and time is required to show what place these modifications of existing radiation methods will take in the treatment of vesical carcinoma.

The practical difficulties of applying X-ray therapy to the bladder have so far rendered this method ineffective, except sometimes for controlling hæmorrhage, but there is scope for further efforts.

MEASURING THE GROWTH

It has been our custom in this country to have a physicist present in the theatre to estimate the dosage required in relation to the size of the growth. When the growth is extensive and occupies an arc of a circle, the dimensions can only be accurately estimated with a malleable measure. Callipers are useless. I use a piece of lead tape about 8 cm long and graduated in 0.5 cm lengths (fig 4). This, too, was made for me by the Endoscopic Company.

SUMMARY

All patients with vesical papillomata should undergo regular cystoscopic inspection indefinitely.

Papillomata without cystoscopic features of carcinomata, ascertained after careful investigation, should be treated by cystoscopic diathermy.

It is generally not possible to distinguish cystoscopically between simple papilloma and non-invasive papillary *carcinoma*.

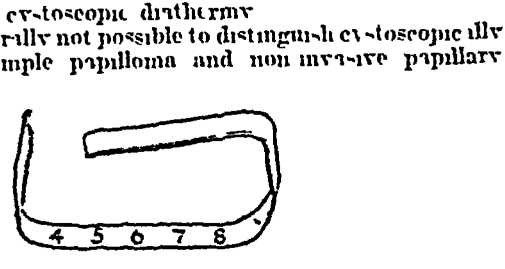

Fig 4—Malleable metal tape-measure for bladder growths

It is essential that a cystoscopist should be able to recognise the early signs of invasive carcinoma.

The lack of biopsy details, showing whether the growths in question are infiltrating or not, is a weakness in many statistical reports.

It is not possible to assess immediate prognosis merely on a histological grading classification of already infiltrating tumours.

Is the growth infiltrating or not? This is the question of overriding importance in prognosis. If the growth is infiltrating, the extent to which it infiltrates is the next most important factor.

In trying to balance the claims of one form of treatment against another, it should be borne in mind that the substitution of the large bowel for the urinary bladder generally shortens life.

The results of radium treatment are better than those of cystectomy.

Evidence is lacking that radon seeds have any more than a palliative action on invasive growths.

Metals and fluids rendered radioactive artificially are being used experimentally.

SOME DEVELOPMENTS IN THE TECHNIQUE OF TRIGEMINAL INJECTION

JOHN PENMAN
M.B. Lond., M.R.C.P.

NEUROLOGIST, HERTFORD COUNTY HOSPITAL; CLINICAL ASSISTANT, ST. GEORGE'S HOSPITAL, LONDON, AND THE MAIDA VALE HOSPITAL FOR NERVOUS DISEASES

THIS paper is a sequel to one about *radiological* location of the trigeminal needle (Penman 1949). With the exceptions implied below, that technique is unaltered; the approach used is still the anterior, the X-ray apparatus is still of the Lysholm Schonander type, the basal and oblique projections are those recommended before, and where Harris's guide lines are mentioned the previous nomenclature will be retained.

Choice of Puncture Point

PRE-SELECTION RADIOGRAMS, OR GRID FILMS

Härtel (1912) recognised that the correct puncture point might prove to be anywhere in quite a large area, but stated that the needle should usually enter the cheek opposite the second upper molar tooth. This is a difficult instruction to follow in the living, even when the teeth of that region are present, and many patients requiring trigeminal injection are edentulous.

Harris (1937) recommended that downwards from the most lateral part of the bony margin of the *orbit* one should draw a line parallel to the median plane of the face, and take the highest point on that line at which one could conveniently press a finger tip inwards and upwards beneath the lower border of the maxilla. The puncture point thus defined is usually at a height about midway between those of the ala nasi and the *angle of the mouth*; it is widely used, serves extremely well in average cases, and in this paper will be called the conventional puncture point. There are two *opposite* extremes, however, at which it becomes ineffectual. Sometimes the anterior surface of the petrous bone is so steep and the foramen ovale faces so much downwards that a needle inserted at the conventional point will either fail to enter the foramen at all, or enter it but immediately jam on the petrous bone, or at best lie so close against the petrous bone as to be underneath the trigeminal sensory root. Less often the anterior petrous

NEW CONCEPTS OF POLIOMYELITIS *

PATRICK N. MEENAN
M.D. N.U.I., D.C.P.
BACTERIOLOGIST, ST. VINCENT'S HOSPITAL, DUBLIN

> "POLIOMYELITIS is a common virus disease which usually runs a mild course characterised by upper respiratory or gastro-intestinal symptoms but occasionally the picture is complicated by signs indicating invasion of the C.N.S. . . ." (Howe 1952).

This definition, which may still appear unusual to some, underlines the change of emphasis in the study of poliomyelitis in the last few years. The accident of paralysis has been placed in its proper perspective, and we now view the whole disease—or what we think is the whole disease—instead of concentrating too much on one facet of it.

Three different immunological types of poliomyelitis virus have so far been described—namely, Brunhilde (type 1), Lansing (type 2), and Leon (type 3). The adaptation of the Lansing type to mice has enabled antibody surveys to be made with relative ease by means of neutralisation tests, and the results have confirmed recent ideas about the epidemiology of poliomyelitis (Meenan 1951). The virus is widely distributed and occurs in all climates. Antibodies to all three strains have been demonstrated among communities as remote from one another as Eskimos (Paul et al. 1951) and Africans (Howe 1952).

These surveys have usually been made with the Lansing strain only, but there is reasonably good evidence that the distribution of antibodies to it closely parallels the distribution of poliomyelitis virus, independent of strain differences. The average age at which poliomyelitis is acquired in any given community seems to be the same as the average age of acquisition of Lansing antibodies (Gear et al. 1951). The relationship cannot be taken as absolute, and one cannot use survey results as a universal index of the immunity of any given population. In future surveys more than one type of antibody should be tested.

Large epidemics of paralytic poliomyelitis seem to be a reflection of the improved living and sanitary conditions of the countries which suffer them. In most parts of the world poliomyelitis epidemics are small or unimportant; and paralysis, when it occurs, is almost limited to children under 5 years old. As the virus is liberally distributed, nearly everybody comes in contact with it before that age, and progressively acquires enough resistance to make a paralytic illness unlikely. On the other hand, in a person not protected by previous exposure to the virus, the likelihood of paralysis rises during childhood, being lowest in infancy and reaching a peak in early adult life. As research on the virus has been almost exclusively carried out in countries where the disease *is* epidemic rather than endemic, we have come to think of epidemics as the natural host-virus relationship. But the reverse appears to be actually the case. Instead of coming recently to prey on man, the virus seems rather to have lived in more or less harmonious relationship with us for centuries; and it is we who, by altering our living conditions, have upset the balance.

To offset this gloomy picture it is commonly held that there is a mechanism of natural immunisation, even in those countries which are now subject to epidemics. Turner et al. (1950) suggest that there are a thousand subclinical infections with the Lansing strain for every clinical case of poliomyelitis, and Howe (1952) says that for every paralytic case amongst those reaching the age of 20 there have been a hundred non-paralytic or abortive cases. Brown et al. (1952), however, hold that the distribution of virus, even during epidemics, is confined to close contacts of cases, such as members of their families. If this is so, the need for a safe and efficient method of prophylaxis is even greater than was thought.

Prophylaxis

The use of vaccines and of gamma-globulin in the prevention and control of paralytic poliomyelitis has been discussed in academic fashion for several years. So satisfied, however, were all workers in this field of the strict neurotropism of the virus that there seemed to be little theoretical justification for their use. It is true that Enders et al. (1949) had grown the virus in tissue culture free from neural elements, but it remained for Horstmann (1952) and Bodian (1952a) to give fresh direction to our study of the disease pattern. By the demonstration of a viræmia in the experimental disease they may have brought poliomyelitis into line with what we know of some of the other virus diseases instead of its being a complete enigma. The virus had, of course, been looked for in the blood of patients, but the finding that antibodies were present to a high titre at the onset of paralysis was taken as confirmatory evidence that it did not travel by this route. Two isolations from the blood of patients have been reported (Ward et al. 1946, Koprowski et al. 1947) in one of which the virus was recovered less than six hours after the onset of an abortive illness. In retrospect it looks as though in many cases virus was not isolated because it was sought too late.

EXPERIMENTS ON MONKEYS

Most of the recent work on poliomyelitis has been done on chimpanzees, which seem to react to infection much as man does. Simple feeding of the virus to these animals leads to a high rate of alimentary infection and a low rate of paralysis, and the clinical and pathological features of poliomyelitis appear to be the same in both species. In Horstmann's (1952) work virus was isolated from the blood of 5 of 8 chimpanzees which, after feeding, had no apparent disease. It was recovered between the fourth and the sixth day. Bodian (1952a) infected 4 chimpanzees, with very interesting results:

> 2 of them became paralysed after thirteen and seventeen days, and virus was isolated from the blood-stream on the eighth and fifteenth days respectively. In a 3rd chimpanzee the virus was present in the blood on the eighth day and again on the eleventh day; the chimpanzee showed no clinical sign of infection, but histological lesions were present in the central nervous system on the fifty-ninth day. In the first 2 chimpanzees antibody was present to a high titre at the time of paralysis. The response was lower in the 3rd chimpanzee but by no means negligible by the fifteenth day. In all 3 the virus was present in the fæces.
>
> The 4th chimpanzee reacted differently. No virus was isolated from the blood on the eighth day, the antibody response was slow, and no evidence of involvement of the central nervous system was found after sacrifice on the seventy-second day. On the other hand, the excretion of virus in the fæces appeared to be greater and more prolonged than in the 3 other chimpanzees. A high titre of antibody did not seem to affect virus excretion. This animal, the only one in which a viræmia could not be demonstrated, was the only one in which the central nervous system was not affected.

Other evidence, from experiments in cynomolgus monkeys, is also available (Bodian 1952b):

> After 23 were fed virus on three consecutive days 12 became paralysed and 11 remained well. A viræmia was demonstrable on the seventh day in 6 of those 12 which subsequently became paralysed but in none of the 11 others. Later bleedings, on the day of paralysis, in 7 of the monkeys revealed no viræmia.

Further experiments can be summarised to show a striking and suggestive difference between the level of porates a device introduced by Luer about 1860 but long regarded as unnecessary on ordinary syringes—a *threaded stem and a milled runner*, which can be used as a check against injecting more than a predetermined quantity of liquid (Dr Wilfred Harris has for many years used the same device on a shorter, broader 1-ml syringe)

---

* Based on a paper read before the section of pathology of the Royal Academy of Medicine in Ireland on Jan. 16, 1953. The full text will appear in the *Irish Journal of Medical Science*.

Location of Injected Alcohol

MIXTURE OF ALCOHOL WITH RADIO-OPAQUE MEDIUM

While one is using radiography to guide the needle, an opportunity would be missed if one did not also try to gather some evidence of the situation of the injected alcohol A mixture of 4 parts by volume of absolute ethyl alcohol with 1 part of a synthetic iodine compound ('Myodil') has been manufactured for that purpose In the presence of even a trace of water the two ingredients separate, and the syringe into which the mixture is drawn must therefore be carefully dried, for the special syringe described above a handy drying implement is an ordinary pipe cleaner, autoclaved For drawing up the mixture it is best to use a short fine intradermal needle, its socket must be dried out before it is fitted to the syringe, which must next be used to force air outwards through the needle shaft until that also is dry

After injection of 0 10 ml of this mixture, radiograms in the basal and oblique projections may show a variety of appearances Not infrequently the opaque medium is seen scattered in the posterior fossa, in that event, even though for the first five or ten minutes there may have been satisfactory trigeminal sensory loss, one can be sure that no lasting success has yet been achieved In other cases the opaque medium forms a close network of minute globules within a small and roughly circular area anteromedial to the needle tip, in which event one can be fairly sure that the sensory loss will be permanent As soon as the mixture leaves the needle its ingredients separate, the alcohol tending to float upwards and the opaque medium to sink, with the result that there is only indirect evidence of the location of the alcohol, nevertheless the empirical value of this method is considerable

A serious danger must be mentioned the mixture may be mistaken for the pure opaque medium and offered as such to a doctor to inject intrathecally before myelography This has happened once, when only exceptional *vigilance prevented a presumably* lethal injection of absolute alcohol into the cisterna magna The following precautions should be observed

(1) The mixture must be supplied in ampoules containing not more than 1 ml (media for myelography are usually supplied in 3-ml ampoules)

(2) Each ampoule, not merely each box containing a batch of them, must be labelled "Absolute alcohol with myodil [or whatever the trade name may be] for trigeminal injection only," the more dangerous ingredient being mentioned first

(3) Preferably the whole stock of the mixture in a hospital should be under lock and key apart from stocks of other substances kept in the operating theatre

Conclusion

With these supplementary aids injection of the trigeminal sensory root remains a difficult and often a lengthy procedure, but its chief object—lifelong trigeminal anæsthesia for relief of tic *douloureux*—is achieved with less discomfort to the patient and greater certainty.

The mixture of alcohol with a *radio opaque medium* is the invention of Dr James Bull, to whom I am most grateful for his help and encouragement in all radiological aspects of trigeminal injection In the initial construction of the trigeminal grid Miss Susan Browne gave valuable assistance, for which I take this opportunity of thanking her For the rest of these aids to injection I am solely responsible

The grid films and the mixture of alcohol with a radio-opaque medium were first described publicly, though only *orally, at a meeting of the Society* of British Neurological Surgeons on July 22, 1949[†] None of the other aids has been described before

The ten millimetre stop is an extremely simple device which can be manufactured by any good surgical instrument maker The special 1 ml syringe is made by Messrs Down Brothers, Mayer & Phelps The mixture of alcohol with myodil is supplied by Messrs Glaxo with precautions (1) and (2) recommended above

CORRECTION

This is an appropriate place for pointing out an inaccuracy in my earlier paper (Penman 1949), in which ossified ligaments adjoining the foramen ovale were referred to as if they were all of one type Chouké (1946, 1947, 1949) has shown conclusively that there are two ligaments, the pterygospinous and the pterygo alar, which differ in origin, frequency among white people and Negroes, angle, and relation to the foramen I am much obliged to Dr Chouké for personally drawing my attention to this distinction

ALCOHOL PAIN IN HODGKIN'S DISEASE

JØRGEN BICHEL[‡]
M D Copenhagen
PROFESSOR OF GENERAL PATHOLOGY IN THE UNIVERSITY OF AARHUS

POUL BASTRUP-MADSEN[‡]
M D Copenhagen
SENIOR ASSISTANT PHYSICIAN, MARSELISBORG HOSPITAL, AARHUS, DENMARK

FOUR years ago a patient with Hodgkin's disease, whose tolerance to alcohol was considerably reduced, was admitted to the Radium Centre, Aarhus At *that time the lymphogranulomatous processes* were mainly localised in his lungs The patient said that ingestion of very small quantities of alcohol, such as a glass of mild beer (alcohol content about 1%), produced pain in the left side of the chest The pain developed a few minutes after the ingestion and persisted for about an hour.

Since that time we have invariably questioned our patients with Hodgkin's disease or other hyperplastic disorders of the lymphoid tissue about their tolerance of alcohol We found this symptom, which we have termed "alcohol pain," in 9 of 62 patients with Hodgkin's disease We were at a loss to explain the mechanism of production of alcohol pain, and were for a long time *in doubt whether it was a specific symptom* of Hodgkin's disease Since similar findings have been published by other workers (Hoster 1950, Verbeeten 1952), we report these 9 cases here

CASE-RECORDS

Case 1 —A *man, aged* 29, noticed enlargement of his cervical lymph nodes for the first time in 1945 Histological examination of an excised lymph node in 1946 revealed Hodgkin's granuloma At that time radiography of his chest did not show any abnormalities Six months later he complained of a sense of oppression in the chest and radiography revealed a slightly blurred pulmonary *pattern but* by those cases which show the "illness of infection," and some such course of events could explain the early appearance of antibodies. In the chimpanzee antibodies can sometimes be detected before virus can be recovered from the stools (Melnick 1951). As already mentioned they have often been found by the time paralysis supervenes. Alternatively, the infection may be entirely peripheral and superficial, with virus growing in the nasopharynx and the intestine, and sufficient virus being absorbed from these sites to produce immunity or to enter the central nervous system.

[†] A reproduction of a grid film without any account of its use was published in *Radiography* 17 157 This was done without my agreement and by an error for which apology has been made

[‡] Aided by grants from the Anders Hasselbalch Anti Leukæmia Foundation and C P Schepler and Wife's Bequest the Irma Foundation

The fundamental difficulty is to know how far experimental findings can be applied to natural infection in man. What is the relation between the disease in animals produced by large doses of laboratory-adapted strains and that in man produced by small doses of naturally occurring virus? Whether or not alimentary reinfection can be established in the immune subject may be a question of dosage.

The experimental action of gamma-globulin suggests that spread by the blood-stream to the central nervous system may be important, because quite low levels will prevent paralysis; but the findings in man are still too few to be significant. Not all chimpanzees with viræmia develop paralysis (Bodian 1952b). At a maximum of 50, the number of second attacks is very small by comparison with the vast number of paralytic cases reported, and it is generally accepted that they are due to an antigenically different strain from that which caused the first. Be that as it may, it has been accepted for years that poliomyelitis virus can travel in nerves, and we have no right to assume that virus found in them is always travelling centrifugally. What has not, perhaps, been demonstrated so convincingly is that in natural poliomyelitis the virus does travel by the nerves.

To conclude, however, I must point out that, though theoretical musings are refreshing, and the need to remove poliomyelitis from the vacuum in which it has too long languished away from other virus infections is urgent, they remain theoretical. In no disease is it so difficult to see the wood for the trees, and all one can do is to point out lines of research which must be interesting and may well be rewarding. In the half-century of poliomyelitis study we have discarded the theory of lymphatic spread. We now seem to be reaching a phase where the theory of neurotropism is weakening and hæmatogenous spread is coming to the front. Perhaps, as so often happens, the truth lies in a synthesis of all three, as already outlined.

Basis for Control?

One of the attractions of the theories under discussion is that they provide a rational basis for the control of paralytic poliomyelitis by ordinary immunological means. Indeed, the work on vaccines and gamma-globulin is an act of faith in them. Antibodies so produced or provided will be of little value unless they come in contact with the virus, and the blood-stream seems a far more likely place for this to happen effectively than the central nervous system. These theories must also derive support from recent epidemiological findings. Widespread and completely silent immunisation seems more likely to be, as in other infections, a function of the usual mechanisms than of completely peripheral infection with only incidental immunity.

Before we build on these foundations, however, let us recognise that they are incomplete. In an attempt to compress a very large subject into small compass it is impossible to examine all its implications; and there are solid reasons why we should not be led too far and too fast. One crucial question has not yet been answered. Is the pathogenesis of poliomyelitis in man the same as in the chimpanzee? We know that the chimpanzee closely simulates man in its reaction to the virus, and that, once infection has been established, the distribution and characters of the lesions in the central nervous system are identical. What we do not know is whether the passage of virus from the intestine to the central nervous system follows the same pattern in the two species. Among the primates, resistance to the virus varies at different portals, although the final picture is the same (Howe 1952). For instance, is the human intestine more or less permeable to the passage of virus than that of a chimpanzee? If there is a viræmia in man, is it easier or less easy for the virus to enter the human central nervous system than that of the chimpanzee? Is the distribution of the virus in space and time within the body the same in both species?

The pace at which poliomyelitis research is moving is almost frightening. With recent technical advances bringing it within the reach of many more laboratories one may expect the near future to be as productive and stimulating as the recent past. If that be so, we may confidently look forward to an era in which man and virus may yet again live happily together, and in which the only apparent complication of infection—paralysis—may be controlled.

TREATMENT OF CARCINOMA OF THE BLADDER

H. P. WINSBURY-WHITE

M.B. Edin., F.R.C.S., F.R.C.S.E.

SENIOR SURGEON, ST. PETER'S AND ST. PAUL'S HOSPITALS, LONDON

THE treatment of vesical carcinoma begins with the regular supervision of simple bladder growths. This is because the danger of malignancy threatens all bladders which have been the seat of merely simple papillomata. This fact is obvious from an analysis of a consecutive series of my own cases, for of 205 of these which were thought not to be malignant and were treated by cystoscopic diathermy 21% ultimately proved carcinomatous.

The passage of time, even of many years, is no safeguard against this menace. On the other hand, there are cases in which simple growths keep on reappearing for years and years without developing invasive characters, as shown by the two following cases.

Case 1.—A woman, aged 68, has been treated by me for papilloma of the bladder by cystoscopic diathermy for more than twenty-three years, having had 65 applications. The last cystoscopy, on Aug. 13, 1952, showed a single pedunculated obtained at another hospital revealed typical Hodgkin's granuloma. X-ray treatment of the involved lymph-nodes evoked a good response. On admission to the Radium Centre in Aarhus in October, 1952, the patient complained of tenderness over the manubrium sterni, where a diffuse and rather firm tumour was palpable. There was moderate enlargement of the axillary and inguinal lymph-nodes on both sides. Chest radiograms did not reveal any infiltrative processes or enlargement of mediastinal nodes, but an area of necrosis the size of a plum, was disclosed in the left upper quadrant of the manubrium sterni. The general condition was good, E.S.R. 19 mm. in 1 hr. (Westergren), Hb 110%. X-ray therapy to the sternum was given, but the tumour did not decrease appreciably in size.

Reactions to Alcohol.—On one occasion during his stay in hospital the patient had a glass of lager with his luncheon. Immediately afterwards acute pain developed over his manubrium and persisted for about ten minutes, radiating down the arms, and was superseded by paræsthesiæ. A few days later the patient again tried to take a glass of lager with his luncheon. An attack of such intense pain developed that he asked for morphine. The character of the attack was as on the previous occasions. At the time of writing no information about the patient's tolerance to alcohol after his discharge has been received.

Case 9.—A young man, aged 20, was called up for military service in August, 1952. About that time he noticed for the first time an asymptomatic swelling in the left supraclavicular fossa. The swelling was rather tender, but as he was otherwise in good health he did not apply for medical aid. While he was on leave in October, 1952, acute pain developed in the region of the tumour and in the entire left side of his chest shortly after he had drunk a glass of lager. He had to go to bed, and a doctor was sent for. He was then admitted to a military hospital; a biopsy specimen from the tumour showed a typical Hodgkin's granuloma, and the patient was transferred to the Radium Centre in Aarhus. On admission here a tumour in the left supraclavicular fossa, the size of two clenched fists, was revealed. Chest radiograph showed no abnormality, and no enlargement of lymph-nodes, liver, or spleen was present. The patient had no fever and the general condition was good; E.S.R. 12 mm. in 1 hr. (Westergren), Hb 83%. The patient is still under treatment.

DISCUSSION

In all the 9 cases reported here the diagnosis of Hodgkin's disease was verified by histological examination of a lymph-node, and the microscopical picture was in all cases typical of Hodgkin's granuloma.

In all the cases pain developed in some part of the body after ingestion of alcohol. The pain was localised to the sites of lymphogranulomatous foci, such as the peripheral lymph-nodes, the mediastinum, and bones. Clinically, it seemed that the pain was localised to the focus which was active at the time. The pain was often very intense and in some cases developed after very small quantities of alcohol, such as a glass of mild beer. The pain invariably appeared a few minutes after the ingestion of the alcohol and persisted for thirty to sixty minutes—i.e., it began as soon as the ingested alcohol was absorbed and persisted until the greater part of it was oxidised. In 2 of the cases it was stated that the tolerance to alcohol was considerably increased after a course of treatment which led to an improvement of the general health. Only alcoholic beverages were stated to induce the pain.

We are at a loss to explain the mechanism by which this pain is produced in Hodgkin's disease. To detect if the pain was excited by the vasodilating effect of alcohol we treated case 7 with various vasodilators (glyceryl trinitrate ointment, histamine hydrochloride, and nicotinic acid amide) but these substances did not produce any pain.

Among many patients with lymphomata of various types the symptom of pain after ingestion of alcohol was found only in those with Hodgkin's disease. At present it is impossible to appreciate the value of the "alcohol test" as a diagnostic aid in Hodgkin's disease. However, in cases where it is impossible to obtain material for a histological examination—e.g., if the disease is localised to the mediastinal lymph-nodes—the presence of the symptom may point to the correct diagnosis, although it must be emphasised that it was only in a small proportion of our patients with Hodgkin's disease that this symptom was present.

SUMMARY

In Hodgkin's disease the ingestion of alcoholic beverages, even in small quantities, often produces severe pain.

The pain is confined to the lymphogranulomatous foci active at the time.

This reaction, which we term "alcohol pain," may sometimes be the initial symptom of Hodgkin's disease and seems to be of some diagnostic value.

Nine illustrative cases are briefly reported.

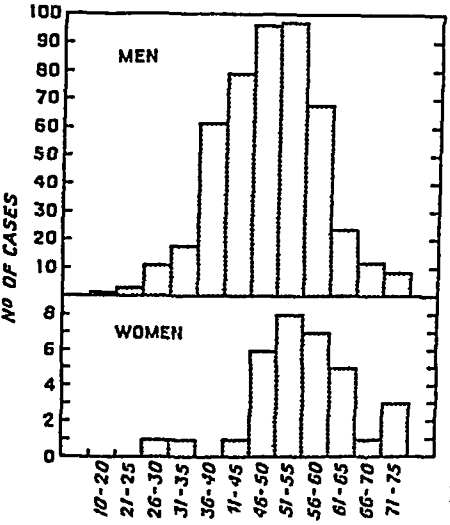
PHLEBOTOMY FOR HÆMOCHROMATOSIS

EFFECT OF REMOVING 52 PINTS OF BLOOD IN SIXTEEN MONTHS

J. C. HOUSTON
M.D. Lond., M.R.C.P.
CLINICAL TUTOR, GUY'S HOSPITAL, LONDON

IT is now known that only negligible quantities of iron can be excreted by the body, and that normally there is a mechanism which prevents excessive absorption of iron from the gut (McCance and Widdowson 1938, Hahn et al. 1943, Granick 1946). The evidence has been summarised by Houston and Thompson (1952). In hæmochromatosis there is probably a congenital defect in the mucosal block for iron. In consequence slightly more iron is absorbed than can be excreted, and the progressive accumulation of iron in the tissues is accompanied, usually about middle age, by the characteristic pathological changes of the disease.

It has been suggested that the rarity of hæmochromatosis in women may be explained by their having, in menstruation and pregnancy, a means of excreting the iron which is absent in men. In patients with hæmochromatosis the tissues contain some 25–50 g. of iron, compared with 3–5 g. in normal people. During the thirty years of reproductive life the average loss of iron through menstruation and pregnancy is probably about 10–15 g. In women with the underlying metabolic defect of hæmochromatosis this loss of iron might be sufficient to delay or suppress the clinical expression of the disease.



Age-distribution of 479 men and 33 women with hæmochromatosis.

Study of the age incidence of hæmochromatosis lends some support to this hypothesis. Women get the disease later in life than do men, and almost always after the

Jacobs, who has practised both methods extensively, are perhaps the most informative. The Glasgow school of urologists (Jacobs et al. 1947) put forward figures which made it abundantly clear that radium implantation was the better method. Fresh data presented by Jacobs at the annual meeting of the British Association of Urological Surgeons in 1952 (not yet published), and at the International Congress of Urology in New York, gave further emphasis to the superiority of radium.* His results are particularly valuable because they embrace the two principal methods—cystectomy and radium—of treating invasive carcinoma. Of his 110 patients treated with radium 33·6% survived five years, whereas the estimated number of five-year survivors after cystectomy (B.A.U.S. series 1952) is 20·5% of 705 cases.*

But other surgeons in this country, who are not practised in the use of radium, have become very expert in the cystectomy-plus-ureter-transplantation technique, and it is with a sympathetic understanding that one notes the rearguard action they continue to fight in this losing battle to support cystectomy.

Comparative figures in different grades of carcinoma, from published results generally, give no satisfaction, because of the lack of information about biopsy. This omission becomes important where many growths are included in which the cellular anaplasia has not yet reached the bladder wall but is confined to the papillomatous protuberance; and it is interesting to note the regularity with which this matter is not discussed.

Moreover the anaplastic non-invasive papillomata are satisfactorily treated by cystoscopic diathermy; so to include these in a statistical report in support of a method of treatment, without any indication as to how many such are included, throws no light on the real problem, which is—what is the best method of treating infiltrating growths of the bladder?

This criticism applies equally to reports on all methods of treatment. Nevertheless, this fault, because it is commonly present, still allows a helpful comparison to be made between the two chief methods of treatment—total cystectomy and radium implantation—which comparison, as has already been pointed out, discriminates so much in favour of radium.

For many years the carcinoma registry of the American Urological Association was content to designate non-invasive papillomata of the bladder as grade-I carcinoma. Although this claim was recently retracted (quoted by Higgins 1952), the mischief of the original classification has been done. The result is that the value of many operative statistics is difficult to assess.

In studying results in relation to higher grades of carcinoma, determined histologically, I can find little encouragement to feel that the lower grades of the invasive groups necessarily give better prognoses than the higher. An obviously important factor is the extent to which infiltration has taken place when the treatment is started, which varies so much in different cases; and the question seems to me to arise whether the lower-grade ones do not give rise to symptoms later than the higher-grades.

To exclude the non-invasive carcinomata from a series of cases is to present undisguised the formidable nature of the problem of treatment of infiltrating growths of the bladder. This is reflected in a series of 57 of my own cases of carcinoma of the bladder which are presented in this form and were all treated by radium implantation or radon. So far as I know, this is the first report of carcinoma of bladder cases made in this way.

Half of the patients were dead before twelve months had passed after the operation; and only 7% survived more than four years, although some have survived three or four years and seem likely to reach the five-year mark. One of them has survived eleven and a half years. I could add a patient who survived twelve years, a man, aged 63, who had a typical early infiltrating carcinoma with ulceration and surrounding thickening; but no biopsy was made, and therefore I prefer to leave him out.

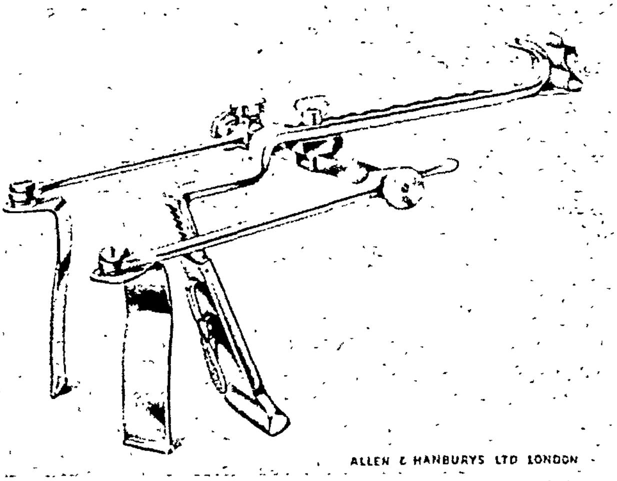


Fig. 1—Bladder retractor. The posterior blade moves up and down on a ratchet, and its lower end does not curve forwards. The lower ends of lateral blades curve outwards.

RADIUM TECHNIQUE

Bladder Retractors.—In recent years, in Great Britain, these have developed along entirely wrong lines for good exposure of bladder growths; they encroach too much on the bladder base, where most growths are situated. Fig. 1 shows a different type of retractor which obviates this defect. It was made for me by Messrs. Allen & Hanburys, of London.

Radium Introducer.—The other point which has worried me is the lack of any sound means of judging whether the encircling needles completely enclose the growth. In the higher grade of malignancy this uncertainty is a potential weakness in radium treatment which requires further research. Palpation through the open bladder often reveals the growth to be very much larger than could be estimated by cystoscopy. The Endoscopic Company, of London, have made for me a long-handled radium introducer with pointed and cupped ends, which are a great advantage for complete insertion of the needles over the old pattern (fig. 2).

RADON

My experience with radon is limited, but I have used it with advantage on occasions. I have never attempted to use it cystoscopically.

Unlike radium, unused units are wasted; often, when the bladder is opened, more seeds are needed than appeared to be required when the growth was viewed cystoscopically; and the chances of success with an infiltrating growth when the radon-seed supply is inadequate are nil.

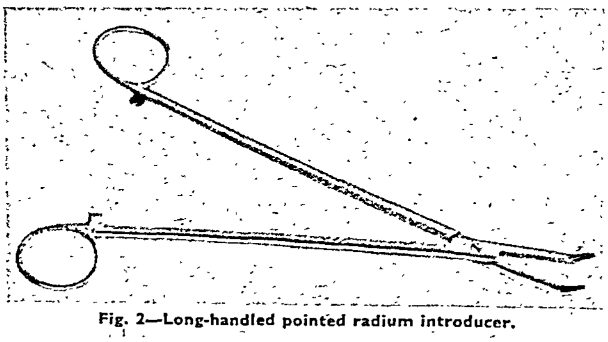

Fig. 2—Long-handled pointed radium introducer.

---

* This figure is reached by combining the 28 patients who have survived five years or more with others still surviving from two to four years whose prospects of surviving for five years are considered to be good.

way of removing iron from the body except by removing blood, which contains 500 mg of iron per litre Hence it is logical to try repeated venesection in patients with the disease

TRIAL OF THE METHOD

A man aged 39, with hæmochromatosis proved by liver biopsy, whose case has already been briefly reported (Houston and Thompson 1952), was bled by venepuncture a pint a week from Nov 22, 1951, to July 3, 1952, since when a pint has been taken every fortnight Throughout this period he has continued at work as a chartered accountant, and at no time has he noticed any ill effects from loss of blood Up to now 52 pints of blood has been withdrawn in sixteen months The patient has not been given any hæmatinics

Table II shows the results of weekly examinations of blood and estimations of the serum-iron and plasma-protein levels None of these has shown any significant alteration The serum-iron level has shown a downward trend but is still above the normal range

DISCUSSION

Granick (1949) was probably the first to suggest that repeated venesection might be beneficial to patients with hæmochromatosis Finch et al (1950) reported that the weekly removal of about a pint of blood for seven weeks caused a progressive fall in hæmatocrit and serum-iron levels in 4 normal men but not in 4 patients with hæmochromatosis Their conclusion is that the rate of blood regeneration after phlebotomy depends chiefly on available body stores of iron Davis and Arrowsmith (1950) and Beyers and Gitlow (1951) have also subjected patients with hæmochromatosis to repeated bleeding without causing anæmia The patient reported here has so far had 52 pints of blood withdrawn in sixteen months, and his blood picture remains normal

Possibly the iron used by the hæmochromatotic in this remarkably rapid blood regeneration may come partly from increased absorption of iron from the gut In the present experiment the patient could not be kept on a low-iron diet, because this would have necessitated a long stay in a metabolic ward However, in sixteen months he has lost 12 g of iron in the blood removed, and not more than a fraction of this can have been made up from his food It seems fair to conclude that his enormous iron stores have been reduced to some extent

Whether he has derived any benefit is a question more difficult to answer There are no satisfactory criteria by which this can be decided But, as patients with hæmochromatosis die from the effects of their disease on vital organs, such as the liver and the heart, and as these pathological effects are probably related to the amount of iron deposited, repeated phlebotomy, started early, might improve the prognosis considerably Bleeding, if properly controlled, is probably free from danger and as no alternative treatment is available, merits at least a long trial Only if a sufficient number of patients so treated are satisfactorily followed up and reported—necessarily by different observers, in view of the rarity of the disease—can its effect ever be finally assessed

SUMMARY

Evidence is presented that repeated phlebotomy may be useful in the treatment of hæmochromatosis

52 pints of blood was withdrawn in sixteen months from a man with proven hæmochromatosis without causing anæmia or other ill effect

Such bleeding may reduce the enormous iron deposits and perhaps improve the prognosis It might with advantage be adopted as the treatment of choice for all early cases, at least until sufficient data have been collected to enable its long-term effects to be assessed

My thanks are due to Prof Max Rosenheim for permission to carry out this therapeutic experiment on his patient , to Dr R. L Waterfield for the blood counts and to Prof R H S Thompson for the serum iron estimations

surface is so close to the horizontal that the same needle, having entered the foramen easily enough, will inevitably pass above the sensory root. There are also less extreme cases in which the conventional puncture point either is a little too high and brings the tip of the needle a little too low in relation to the sensory root, or vice versa. Such cases, whether of the less or of the more extreme kind, are not merely conjectural; radiograms in the oblique projection have often proved their existence.

What we require, then, is a first puncture point which shall at least give the needle a clear run through the foramen ovale and bring it approximately into the right relation with the petrous bone. To this end two devices are combined.

(1) *Härtel's Point and Associated Points*

Härtel (1921) wrote that the axis of a correctly placed needle, if produced backwards, would pass through the vault of the skull at a point which could be found by measuring from the lambda 4 cm. forwards along the sagittal suture and then 2 cm. laterally away from the side of injection. This, which I call Härtel's point, is a reliable guide. In the present procedure it is marked on the scalp with two other points in a plane parallel to the plane of the sagittal suture: one 4 cm. anterior to it, and one 4 cm. posterior to it or 2 cm. lateral to the lambda.

(2) *Trigeminal Grid*

Five straight fine wires, each 4 cm. long, are placed parallel 1 cm. apart; a second set of five similar wires is placed at right angles to the first to form a square 4 × 4 cm., subdivided into sixteen squares 1 × 1 cm. Where the middle wire of each set crosses the other, at the centre of the larger square, a small lead-shot is placed, and the whole is fixed between two layers of washed X-ray film or other suitable transparent material. The grid is then ready for use.

Next, Harris's guide lines are drawn on the patient's face, and the grid is fastened onto his cheek with sticking-plaster. The lead shot must lie over the conventional puncture point, and one of the two middle wires must lie over the elevation line—i.e., the line joining the puncture point to the zygoma point. Three radiograms are now taken in three slightly different projections, for all of which the patient's face rests

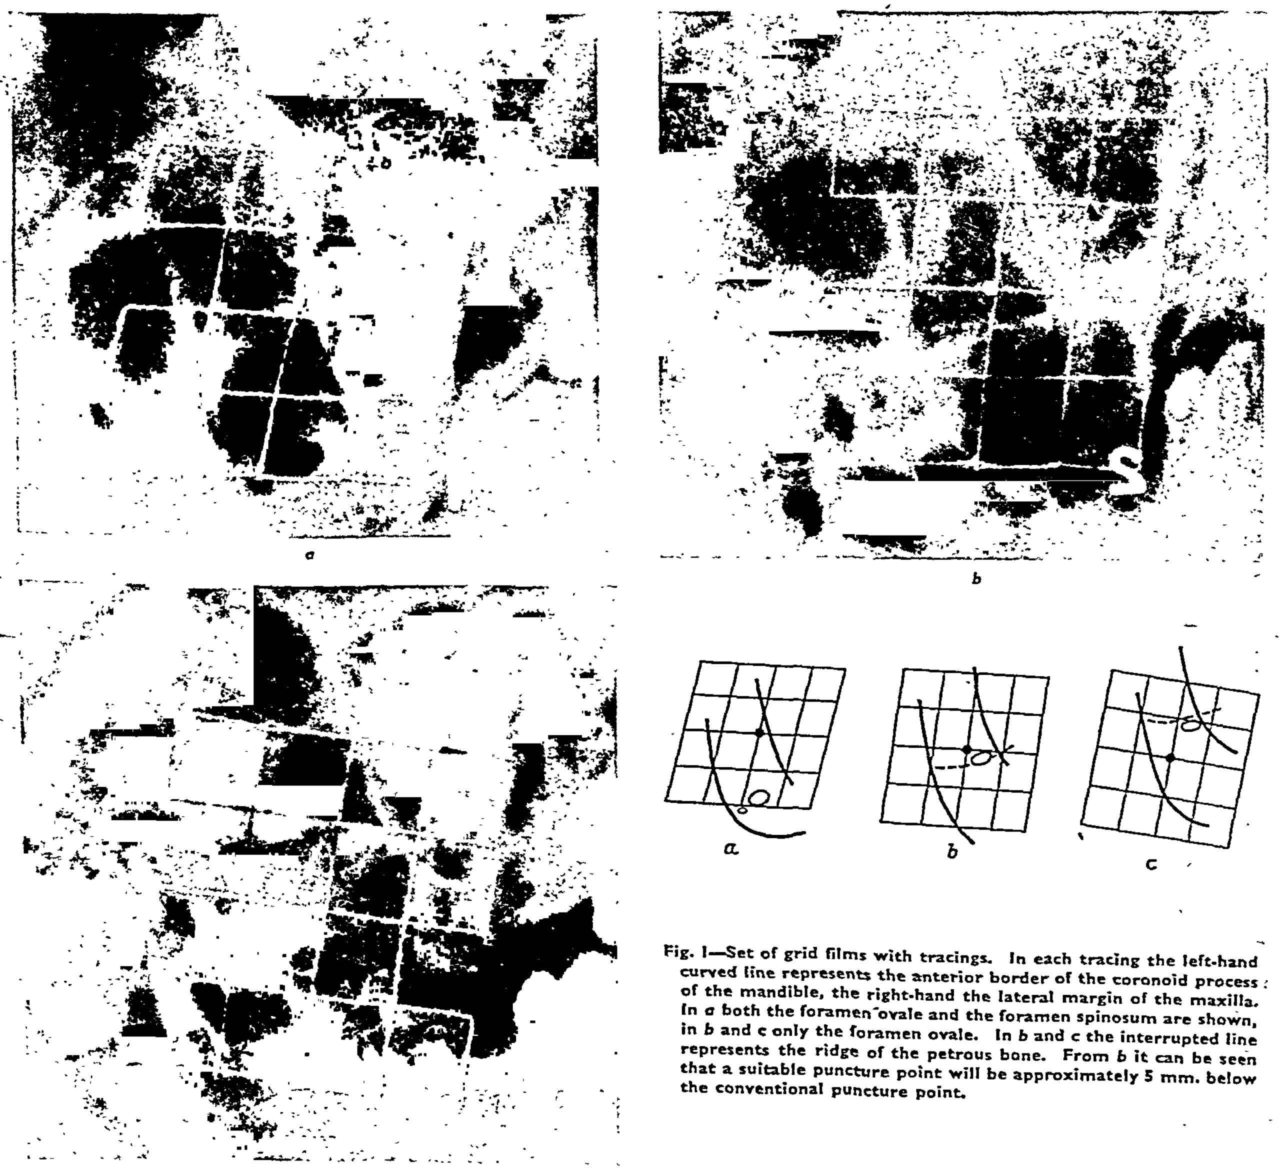

Fig. 1—Set of grid films with tracings. In each tracing the left-hand curved line represents the anterior border of the coronoid process of the mandible, the right-hand the lateral margin of the maxilla. In *a* both the foramen ovale and the foramen spinosum are shown, in *b* and *c* only the foramen ovale. In *b* and *c* the interrupted line represents the ridge of the petrous bone. From *b* it can be seen that a suitable puncture point will be approximately 5 mm. below the conventional puncture point.

TABLE II—MAXIMUM RATE OF URINE FLOW IN PATIENTS THOUGHT TO HAVE ADRENAL DEFICIENCY

Case no.	Diagnosis	Volume of water taken (ml.)	Maximum rate of urine flow (ml. per min.)
7	Anorexia nervosa	1000	6.9
20	"	840	8.4
1[illegible]	Primary ovarian deficiency	900	7.4
21	" "	1000	15.3
22	Myxœdema	1000	6.8
26	"	1000	8.4

(4) The water should be drunk when the oral cortisone activity is greatest, measured by eosinophil depression, and in adrenal deficiency this is about four to eight hours after the cortisone has been taken. If the water is taken when cortisone activity is not greatest, a full diuresis will not result (Oleesky and Stanbury 1951).

As can be seen from table II, in the conditions likely to be confused with hypopituitarism or with Addison's disease, such as myxœdema, primary gonadal deficiency, and anorexia nervosa, the maximum rate of urine-flow after ingestion of a litre of water exceeds 2 or 3 ml. per minute and is normal. Thus these conditions can be clearly separated from adrenal deficiency. The test has been very valuable in establishing or excluding the diagnosis of hypopituitarism.

Conditions in which there may be a failure to eliminate the water load—e.g., heart failure and cirrhosis of the liver (Adlersberg and Fox 1943, Ralli et al. 1951)—hardly enter into the differential diagnosis of adrenal insufficiency. In normal people given cortisone the rate of urine flow in a water diuresis can be increased above the control value (Rosenbaum et al. 1951), but the dose required is huge, 200–500 mg. a day, whereas the dose used in the adrenal-deficient is only 50–75 mg.

The rare salt-losing type of chronic renal disease described by Thorn et al. (1944) can be confused with Addison's disease; in fact it is usually mistaken for Addison's disease. There is a failure of water diuresis, and the Kepler test is positive but usually the blood-urea level is very high, and there is an inability, absent in adrenal deficiency, to produce a concentrated urine. The renal tubules are resistant to 'Pitressin,' deoxycortone, and parathyroid extract and clinically, on the one occasion on which it was given, cortisone failed to alter the course of the disease (Nussbaum et al. 1952). No one has specifically tried to rectify the failure of water diuresis with cortisone, and I have not had the opportunity of trying this, but the available evidence suggests that cortisone will not restore the water diuresis. Thus the salt-losing type of nephritis can probably be separated from Addison's disease by the test as described.

ADVANTAGES

The advantages of the test devised by Soffer and Gabrilove (1952) and of the one described here over the Kepler test are as follows:

(1) They are simpler to perform and less arbitrary.

(2) They do not require any chemical analysis and so can be done in the ward.

(3) They are more specific for adrenal deficiency in that not only is a defect (failure of water diuresis) present in the adrenal-deficient assessed but also the ability of the adrenal hormone known to rectify this defect can be shown.

The test described here has advantages over the test described by Soffer and Gabrilove (1952) in that less time is required and the volume of water drunk can be adjusted to suit each patient. A patient of even moderate intelligence can coöperate by collecting the specimens and noting the times at which they are passed. The only calculation involved—that of the urine flow—is very simple.

SUMMARY

A simple test for adrenocortical insufficiency is described. It is similar to that of Soffer and Gabrilove (1952) but does not require consumption of a large volume of water.

It is suggested that tests of this type should supersede the Kepler test because they are simpler to perform and are more specific indicators of adrenal insufficiency.

Thanks are due to the physicians at the Manchester Royal Infirmary and the Royal Infirmary, Sheffield, for permission to study their patients.

PARATHYROID TUMOUR WITH HYPERPARATHYROIDISM AND COEXISTENT GASTRIC AND DUODENAL ULCERATION

A. ELKELES
M.D. Berlin, D.M.R.E.
CONSULTANT RADIOLOGIST, PRINCE OF WALES'S GENERAL HOSPITAL, LONDON; SENIOR RADIOLOGIST, METROPOLITAN HOSPITAL, LONDON

IT is generally accepted that primary hyperparathyroidism is the result of hypersecretion of one or more of the parathyroid glands, caused usually by an adenoma, occasionally by hyperplasia and hypertrophy, or rarely by a carcinoma of the gland. It is, however, not widely known that an adenoma of the parathyroid may sometimes reach considerable size and may even contain calcium deposits. Some of these large tumours, particularly those located in the upper mediastinum, have been mistaken for substernal thyroid (Hirsch 1937) or aneurysm of the innominate artery (Bergstrand 1931).

In primary hyperparathyroidism the patient's life depends on the diagnosis being made before irreparable damage has been done, particularly to renal function. The following case is recorded (1) because it illustrates the fallacies which may arise in diagnosis; (2) because of the unusually large parathyroid tumour in the upper mediastinum; and (3) because of the coexistence of gastric and duodenal ulceration.

CASE RECORD

A widow, then aged 46, had her left kidney removed in 1941 for multiple renal calculi and hydronephrosis. In February, 1949, she felt a sharp pain in her right upper arm, and radiography revealed a pathological fracture of the upper third of the right humerus. This lesion was attributed to metastases, because radiography showed a round well-defined opacity as large as a big plum in the right upper mediastinum believed to be the primary tumour. The tumour and the fracture were treated by deep radiotherapy 2000r, but neither the size nor the density of this tumour responded to

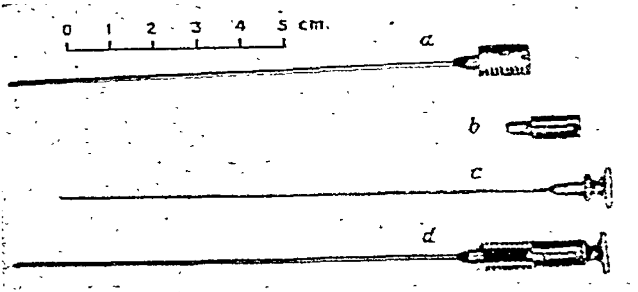

Fig. 3—*a*, 100-mm. needle ; *b*, 10-mm. stop ; *c*, stylet ; *d*, the above three parts assembled.

This difficulty is overcome by means of a stop or distance piece, drilled to allow the stylet of the needle to pass through it, which fits into the needle mount, receives in turn the mount of the stylet, and holds the tip of the stylet exactly 10 mm. short of the tip of the needle (fig. 3). If a film is exposed in the basal projection with this stop in place, the terminal 10-mm. portion of the needle shaft, being hollow, throws a fainter shadow than the rest, from which it can be easily distinguished. The length of the intracranial portion of the shaft is now estimated by comparison with the 10-mm. portion, and this can be done by eye to the nearest millimetre. The intracranial depth required for successful injection is usually 10–15 mm. Before the basal exposure the distance from the zygoma point to the mount of the stylet is measured and written down, and after it the measurement is repeated in case the needle has moved.

The stop must be left in place only during the basal exposure, for there is always a possibility that a small quantity of blood may collect in the hollow terminal portion and clot there. Similarly, needles must not be stored with their stops in place, lest traces of blood should be left in their terminal portions.

The stop enhances the value of the basal projection and shows that even a fairly experienced injector, estimating needle depth merely by touch, may make a large error. The first needle to pass the foramen ovale seldom secures adequate sensory loss ; but, when its depth is so accurately known, a second needle can be inserted beside it to a depth no less accurate. A recent improvement, not shown in fig. 3, is a longitudinal slot in the stop, which enables one to fit and remove it without withdrawing the stylet from the needle.

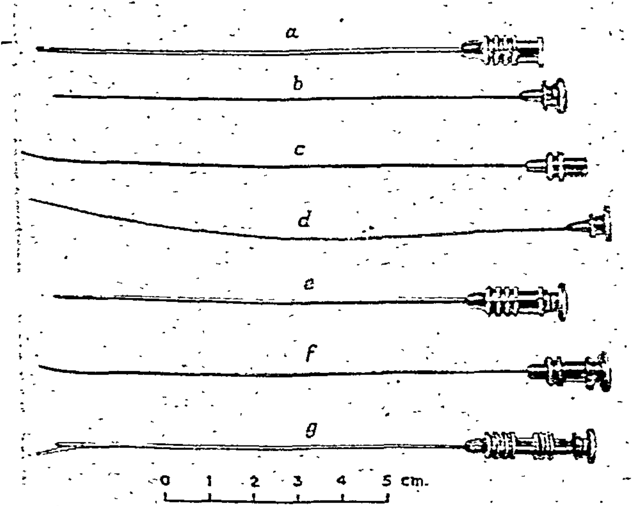

Fig. 4—Double needle : *a*, outer component ; *b*, outer stylet ; *c*, inner component ; *d*, inner stylet ; *e*, assembly of *a* and *b* ; *f*, assembly of *c* and *d* ; *g*, assembly of *a*, *c*, and *d*.

In some cases the sensory root lies so far medial to the foramen ovale that a successful injection can only just be achieved by passing the needle as close as possible to the ramus of the mandible, and in others the sensory root lies so far lateral that the needle has to pass equally close to the maxilla. Hence one can infer that there are also still more extreme cases in which the sensory root lies too far medial or lateral to be reached at all by an ordinary needle.

An analogous difficulty may occur in the vertical plane : the axis of the foramen ovale may be so much steeper than the anterior surface of the petrous bone that a needle passing through the foramen is bound to go above the sensory root. The double needle shown in fig. 4 is designed to reach the root in such cases ; the outer component is first fitted with the outer stylet and passed through the foramen, after which its depth is checked radiologically and adjusted if necessary. Next, the mouth of the outer component is turned in the direction most likely to prove favourable and the outer stylet is replaced by the inner component and inner stylet, which are advanced very cautiously from the moment when they begin to emerge from the outer component. The inner stylet is then withdrawn, and a trial dose of procaine is injected. If success does not follow, the inner component is half-withdrawn, both components are rotated slightly, the inner is advanced as before, and another trial dose is injected.

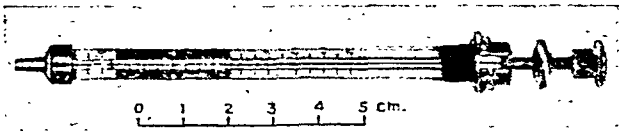

Fig. 5—1-ml. syringe graduated in units of 0·01 ml., with threaded stem and runner.

This needle has succeeded after prolonged failure with ordinary trigeminal needles, and has done so by reaching further medially, laterally, or downwards than they could reach, thus confirming the hypothesis which led to its invention. In so far as it has a greater diameter than they, it may be expected to cause more pain, and therefore it should seldom be used unless there is already analgesia or hypalgesia of the mandibular division. It might also be expected to be more liable to cause hæmorrhage, but that has not been observed. Its rigidity makes it easy to aim. One might well have hoped that it would lend itself to routine use, since the tip of its inner component can be moved in three dimensions without being withdrawn from the foramen ovale, and so ought to stand an improved chance of encountering the sensory root ; but in that respect it has proved disappointing and it by no means supersedes the single straight needle.

Measurement of Small Doses of Procaine and Alcohol

SPECIAL SYRINGE

For injection of the sensory root it is essential to measure the injected fluids to the nearest 0·01 ml. A suitable trial dose of 2% procaine is 0·03 ml., and a suitable individual dose of alcohol (though it may be repeated five or ten times in all) is 0·05 ml. With such doses one must know, and allow for, the exact capacity of the mount and shaft of the needle, which in the case of 100-mm. needles is usually 0·06 or 0·07 ml.

The syringe shown in fig. 5 is new only in the limited sense of being a fresh combination, so far as I know, of two earlier designs. As regards capacity and shape, it is of the type known as Waller's long vaccine syringe, which holds 1 ml. and is long and narrow enough to be graduated in units of 0·01 ml. In addition it incor-

11 tumours in the anterior and 5 in the posterior mediastinum Thus, the differential diagnosis of a round mass in the upper anterior or posterior mediastinum should include parathyroid tumour

In the present case the malignant character of the mediastinal mass was doubted by me for the following reasons (1) the tumour was well circumscribed and had a calcified rim, (2) it had displaced the trachea below the sternum, but there was no evidence of infiltration into the neighbouring structures, (3) comparison with previous chest radiographs showed no appreciable change in size and density of the tumour, and (4) the tumour had shown no response to deep X-ray therapy These findings, combined with general osteoporosis, fibrocystic changes in some bones, healed pathological fractures, and a history of multiple renal calculi of the left kidney and of calcified deposits in the right kidney led to the diagnosis of hyperparathyroidism This was confirmed by the high serum-calcium level of 22 mg per 100 ml and the lowered plasma phosphate level of 2 5 mg per 100 ml

In the final stage parathyroid poisoning (serum-calcium 22 mg per 100 ml) with renal failure (blood-urea 312 mg per 100 ml) were present However, the clinical picture was complicated by severe epigastric pain, the cause of which was gastric and duodenal ulceration Rogers (1946), Rogers et al (1947), and Robinson et al (1951) have drawn attention to the common occurrence of duodenal ulcers in hyperparathyroidism These workers suggest that the association of hyperparathyroidism with duodenal ulcer is too common to be merely coincidental, but so far they have been unable to explain the relationship The severe calcification of the abdominal aorta found in this case and the occurrence of arteriosclerosis in hyperparathyroidism may perhaps offer a clue to this association My radiological investigations of the pathogenesis of gastric ulcer in patients over 50 years of age have suggested that arteriosclerosis plays an important part in its pathogenesis (Elkeles 1949, 1950) In a high proportion of gastric ulcer cases calcification of the abdominal aorta was found I pointed out that, although the same does not apply to duodenal ulcer in general, those ulcers which develop in later life may also be due to arteriosclerosis I therefore suggest that a causal relationship exists between arteriosclerosis and the occurrence of gastric or of duodenal ulcer in hyperparathyroidism

Peptic ulceration is an important complication in hyperparathyroidism from the therapeutic standpoint In the present case the patient had been kept, for three months before admission to hospital, on a strict milk diet Albright and Reifenstein (1948) emphasise that a high blood-calcium level may easily lead to parathyroid poisoning when a high-calcium diet is given In this patient, therefore, the milk diet may have precipitated parathyroid poisoning with renal failure

SUMMARY

A case of primary hyperparathyroidism with a large partly calcified parathyroid tumour in the upper mediastinum and coexistent gastric and duodenal ulceration is described

The difficulties which may arise in the diagnosis of hyperparathyroidism are discussed

Parathyroid adenoma should be included in the differential diagnosis of tumours located in the upper mediastinum

Attention is drawn to the common association of hyperparathyroidism with gastric or duodenal ulceration, and to the danger of a strict milk diet, which may precipitate parathyroid poisoning

---

I wish to thank Dr J Browning Alexander for permission to make use of the clinical records of this patient, and Dr Donald Hunter for his keen interest in this case and for confirming the diagnosis The case was referred to as case 5 by Mr J E Richardson in his Hunterian lecture to the Royal College of Surgeons of England on Feb 19, 1953

GROWTH OF BACTERIA IN INTRAVENOUS INFUSION FLUIDS

L MICHAELS
M B Lond

B RUEBNER
M B Edin

JUNIOR CLINICAL PATHOLOGISTS, BRISTOL ROYAL INFIRMARY

COMPLICATIONS of intravenous infusion are not uncommon Overloading of the circulation, thrombosis of the vein (Bolton Carter 1951), and infection of cut down wounds are well recognised mishaps We draw attention here to the possibility of a dangerous reaction caused by bacterial growth in the infusion fluid during the infusion This complication we have met twice within two years Both patients developed serious pyrexia while on intravenous infusion therapy lasting several days, and in each case large numbers of coliform bacilli were found in the infusion fluid These organisms are unlikely to have been present originally in the fluid

CASE-RECORDS

Case 1 —In May, 1950, a woman, aged 43, after an operation for excision of rectum, received intravenous therapy consisting of glucose and physiological saline solution On the second postoperative day, while still receiving the infusion, she developed an increase of pyrexia, for which no obvious clinical cause could be found Her temperature reached 103 2°F and remained raised for thirty six hours, but when the infusion apparatus was taken down the temperature settled rapidly (fig 1)

Investigation —0 5 ml of fluid was taken with sterile precautions from the tube of the giving set and cultured immediately on 5% horse-blood agar A profuse pure growth of a coliform bacillus was obtained Fluid taken from the bottle at the same time gave a very scanty growth of the same organism

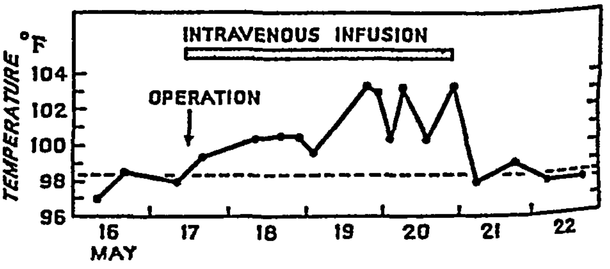

Fig 1—Treatment and temperature-chart of case 1

This organism grew both at room temperature and at 37°C, but better at 37°C It was non motile It fermented lactose saccharose maltose and mannitol with production of acid but not gas The Dulcitol was not fermented Indole was not produced The methyl red test was positive The Voges Proskauer reaction was negative The organisms grew in Koser's citrate medium

This organism therefore belonged to the anaerogenes group of coliform bacilli

The rubber tubing was opened throughout its entire length No flaws were detected and no clots were seen apart from some small ones in the shank of the needle

Case 2 —In June, 1952, a woman, aged 31, had intravenous infusion therapy continuously for three days during an no enlargement of the mediastinal lymph-nodes. A year later itching of the skin and a cough with production of sputum had developed. Radiography in 1948 showed enlargement of the lymph-nodes in the right hilar region. During the next few years the patient complained of progressive fatigue, dyspnœa, and lumbar pain radiating down the legs. Chest radiograms from March, 1950, revealed a wide mediastinal shadow. In 1951 dyspeptic symptoms developed, and a peptic ulcer was disclosed radiographically. Since the diagnosis of Hodgkin's granuloma the patient has for periods received treatment with X rays or with nitrogen mustards. The general condition has fluctuated, but each renewed course of treatment is still followed by a satisfactory remission.

Reactions to Alcohol.—Since 1944 the patient has been unable to tolerate alcohol. At first a sense of oppression in the chest developed, sometimes accompanied by retrosternal pain, when he drank a bottle of lager (375 ml., alcohol content about 3%). At the examination in 1951 he stated that ingestion of alcohol led to a sensation of suffocation and development of the aforementioned pain. He also complained of lumbar pain radiating down the right thigh posteriorly; the pain developed two or three minutes after he had had a glass of schnapps and persisted for about twenty minutes.

Case 2.—A woman, aged 26, noticed enlargement of her cervical lymph-nodes for the first time in 1944. Histological examination of a biopsy specimen from a lymph-node showed Hodgkin's granuloma. Before her admission to the Radium Centre in Aarhus she had received five courses of X-ray therapy to both sides of the neck, the thorax, the spine, and the left greater trochanter. On admission here in February, 1950, she was rather weak, with a fluctuating temperature and erythrocyte-sedimentation rate (E.S.R.) 120 mm. in 1 hr. (Westergren). Firm and slightly enlarged lymph-nodes were noticed on both sides of the neck, in the right axilla, and in the right inguinal region. Radiography revealed destruction of the right transverse process of the second thoracic vertebra and of the right clavicle, a defect of the third lumbar vertebra, a nodular density in the ilium, and large infiltrations in both lungs. Some improvement resulted from treatment with triethylene melamine. In September, 1951, she was rather weak and said she had been bedridden during the greater part of the period since admission to hospital. Radiography showed necrosis in the right humerus.

Reactions to Alcohol.—At this examination the patient said that for the last three years she could not tolerate alcohol. Immediately after the ingestion of a glass of wine or a bottle of lager intense pain developed in the affected areas, mainly on the anterior aspects of the lower extremities; the pain generally persisted for fifteen minutes.

Case 3.—A man, aged 26, fell ill in 1949 with enlargement of the lymph-nodes in the left axilla, pain in the right shoulder radiating to the arm, and itching. Histological examination of an excised lymph-node showed Hodgkin's granuloma. On admission in January, 1949, to the Radium Centre in Aarhus he had slight enlargement of the lymph-nodes of the neck and supraclavicular fossæ. Radiography revealed a mediastinal tumour but no infiltrations in the lungs. The E.S.R. was 34 mm. in 1 hr. (Westergren). During the next three years he was treated repeatedly, partly with nitrogen mustards and partly with arsenicals and X rays.

Reactions to Alcohol.—As early as a year before the patient fell ill he had noticed that the ingestion of alcohol caused immediate pain in the right side of his chest, rather liberal quantities being necessary to produce the pain at first. Immediately after a course of nitrogen mustards in 1951, during which his general health improved, he could again tolerate alcohol, but a month later small quantities of lager produced pain in the right side of his chest.

Case 4.—A woman, aged 24, noticed enlargement of the lymph-nodes of her neck and later also of her right axilla in 1947. In October, 1948, she was admitted to the Radium Centre in Aarhus. In addition to the enlarged lymph-nodes a mediastinal tumour was found by radiography. Histological examination of a biopsy specimen of a lymph-node showed Hodgkin's granuloma. The patient received a course of nitrogen mustards. In February, 1949, she was readmitted with a complaint of constant oppression in her chest and pain in her right arm. X-ray therapy was given. In January, 1950, the mediastinal tumour had increased, and a month later radiography showed necrosis in the sternum. At that time the patient stated that burning retrosternal pain developed whenever she drank wine or beer. Usually the pain developed in a few minutes and persisted for up to half an hour

Case 5.—A man, aged 34, noticed enlargement of the lymph-nodes of his right supraclavicular fossa for the first time in 1947. Examination at the Radium Centre in Aarhus in February, 1948, revealed enlargement of the lymph-nodes of the neck and the supraclavicular regions. Chest radiography showed enlarged hilar shadows with perihilar infiltrations. Histological examination of an excised lymph-node from the lateral cervical region showed Hodgkin's granuloma. The patient received a course of nitrogen mustards and, later, one of X-ray therapy. An examination six months later revealed atelectasis of the middle lobe of the right lung. A further course of nitrogen mustards was given. A year later gastric symptoms developed. The patient died in March, 1951. At that time there was generalised Hodgkin's disease with skeletal foci.

Reactions to Alcohol.—From October, 1948, the patient could not tolerate alcohol. Immediately after the ingestion of even very small quantities of alcohol intense pain developed over the lower thoracic region. He noticed this pain for the first time once when he had had a glass of mild beer with a meal. Thereafter pain developed whenever he took an alcoholic drink; merely one or two mouthfuls of lager could induce the pain, which persisted for half an hour. For prophylactic reasons he had occasionally taken two analgesic tablets when he intended to have a glass of lager. On one occasion when he had drunk a glass of red wine he had to lie down owing to intense pain. The pain was not accompanied by nausea or vomiting. Even immediately after the end of a course of nitrogen mustards he could not tolerate small quantities of alcohol.

Case 6.—A man, aged 28, fell ill in 1948 with enlargement of the cervical lymph-nodes. Shortly afterwards pain developed over the sacral and left gluteal regions. Radiography revealed enlarged lymph-nodes in the hilar regions but no osseous abnormalities in the pelvis and hips. Histological examination of an excised lymph-node showed Hodgkin's granuloma. During the next year dyspnœa on exertion and progressive lumbar pain developed.

Reactions to Alcohol.—At the time when the diagnosis was established the patient could drink a bottle of lager without any subsequent pain, but six months later intense pain developed in the lumbar region and over the sacrum after ingestion of even very small quantities of alcohol.

Case 7.—A woman, aged 52, fell ill in 1951 with swelling below the right clavicle and transitory swelling of the right arm. Six months later intense itching of the skin developed. On admission to Marselisborg Hospital in September, 1952, she had an ill-defined swelling below the right clavicle, the size of a clenched fist, and a slightly enlarged lymph-node in the right axilla. There were numerous scratch marks on the skin. Histological examination of an excised infraclavicular lymph-node showed Hodgkin's granuloma.

Reactions to Alcohol.—Shortly after the onset of the disease the patient had noticed that pain developed in the right arm almost immediately on ingestion of small quantities of alcohol; even beer with an alchol content of 1% could induce the pain. During her stay in hospital such an attack of pain was provoked by oral administration of 10 ml. of 50% alcohol. Five minutes later intense pain developed in the right shoulder and arm and persisted for an hour.

Investigation.—To find out if the pain might be due to vasodilation by the alcohol, various other vasodilators were administered. Glyceryltrinitrate ointment was applied to the skin over the enlarged lymph-nodes, but no pain developed. A subcutaneous injection of histamine hydrochloride 0·5 mg. produced a hectic flush of the cheeks and headache but did not excite pain in the shoulder. An intravenous injection of nicotinic acid amide 2 ml. gave similar well-marked symptoms of vasodilation but no pain in the shoulder.

Treatment and Progress.—The patient was subsequently transferred to the Radium Centre in Aarhus, where she was given X-ray therapy to the enlarged lymph-nodes. A month later she was completely well; the itching of the skin had disappeared, and she could tolerate alcohol; even after a large glass of whisky the usual pain in the arm and shoulder did not develop.

Case 8.—A man, aged 31, with a past history of good health, developed an attack of acute pain across the chest, radiating from the manubrium sterni, after having drunk a glass of lager in May, 1951. Shortly afterwards enlargement of the cervical lymph-nodes was observed, and a biopsy specimen through one of two rubber covered apertures in the screw cap of a sterile Winchester bottle containing a little solid mercuric chloride as antiseptic Through the other aperture passed a sterile needle attached, by a short length of rubber tubing on its outer end, to a glass tube containing sterile cotton-wool This acted as an outlet for air but prevented contamination of the apparatus Fluid from the bottle was allowed to run slowly through the tubing into the Winchester bottle at the rate of a slow infusion so that 1 litre bottle emptied in about twenty four hours after which it was changed for a fresh one At the beginning of the experiment and at intervals of twenty-four hours fluid was taken from the needle with aseptic precautions and the viable organisms were counted

Several experiments were made with large and small inocula, and showed that the organisms multiplied in spite of three or more changes of bottle in every case when the fluid was not acid Table III shows the results of several typical experiments As suggested above, the failure of the organisms to persist in the dextrose is presumably due to the low pH of that solution

DISCUSSION

Though it might be thought that the organisms isolated from the infusion apparatus in our cases were already present in the bottles before transfusion we consider this very unlikely The bottles are obtained from a reputable commercial source, and no other infected bottles were discovered during the widely separated periods when these incidents occurred It seems more likely that the infection took place during the infusion, either while the bottles were being changed or by contaminated air sucked into one of the bottles through the air-replacement tube

Coliform organisms are known to be present in the air and dust of wards, and can multiply in simple fluids It is well known that coliform bacilli can use ammonium salts as the sole source of nitrogen and simple carbon compounds as a source of energy Under certain conditions growth can take place in even simpler media Bigger and Nelson (1943) succeeded in growing coliform bacilli in distilled water to which had been added small quantities of talc or other inorganic substances, and they suggested that, under these conditions, the metabolic requirements of the bacilli were obtained from atmospheric ammonia and carbon dioxide We have shown that small numbers of coliform bacilli can multiply in Hartmann's solution with 5% dextrose or in physiological saline solution, under the conditions of an intravenous infusion Once they begin to multiply in the tubing of the infusion apparatus, coliform bacilli may continue to grow, even though the bottles are changed This would happen, however, only if the same giving set were retained In such a case a heavy concentration of organisms can be built up in the infusion set, with serious consequences to the patient

Such a sequence of events should be considered as a possible cause of an obscure pyrexia in a patient on prolonged intravenous therapy

Bolton Carter (1951) has suggested that in prolonged infusions the vein used should be changed periodically to reduce the incidence of thrombophlebitis We suggest that in the course of intravenous infusions likely to last several days a new giving set and a new needle should be used about every twenty-four hours However, if the patient has very few good veins, it would seem permissible to change the giving set but not the needle because the volume of possibly contaminated fluid in the needle and its attached short length of tubing is very small

We should also like to emphasise the importance of strict asepsis during the process of changing bottles as well as when setting up an intravenous infusion Further, we think that the addition of a sterile cotton wool filter to the air replacement tube of the infusion bottle is advisable, to prevent organisms from entering the fluid in the apparatus from the air

A common procedure in many hospitals is to change from a bottle of blood to a bottle of crystalloid solution by simply transferring the rubber bung with its attached clot-filter and giving set Such a procedure increases the risk of contamination of the infusion fluid, because blood is not a sterilised fluid In changing from infusion of blood to infusion of crystalloids, therefore, a fresh giving set should always be used

SUMMARY

Two cases are described in which a patient receiving prolonged intravenous therapy developed severe pyrexia due to growth of coliform bacilli in the infusion apparatus

Small numbers of coliform bacilli (about 10 in one experiment) were introduced into an intravenous infusion running in the laboratory under conditions similar to those of intravenous therapy in patients Considerable multiplication took place when crystalloid solutions such as Hartmann's fluid with 5% dextrose or physiological saline solution were used, in spite of changing bottles

In cases of pyrexia of unknown origin in patients receiving intravenous therapy a bacterial growth in the infusion set should be considered as a possible cause

Attention is drawn to the importance of aseptic precautions in the administration of intravenous fluids

During a long-continued intravenous infusion the giving set and, if possible, the needle should be changed at least once in every twenty-four hours

We wish to thank Mr R V Cooke, F R C S, for drawing our attention to this problem, and Dr W A Gillespie and Dr G K McGowan for their help and advice

MANCHESTER MEDICAL SOCIETY

Abdominal Exploration and Re-exploration

ADDRESSING the section of surgery on March 10 Mr ROBERT COOKE observed that in cases of non penetrating injury of the abdomen exploration was too often deferred disastrously, because either the evidence of visceral injury seemed meagre or resuscitation was deemed inadequate Records of a large hospital showed a failure to recognise a second or third lesion from which death ensued

Diagnostic laparotomy was often a real necessity even today despite the most carefully taken history and the most complete examination, supported by diagnostic aids Even when the diagnosis of gall stones or appendicitis seemed well established, a properly conducted exploration might show that the symptoms were referable to another and more serious lesion Mr Cooke mentioned the tragedies that might result from ignoring the presence of occult blood in the fæces the cause must be ascertained promptly In the newborn intestinal obstruction demanded early exploration to determine the cau since multiple obstructions might be present the inc must be large enough to allow gentle, complete eventration of the bowel, so that the whole picture was seen before corrective surgery was undertaken

Mr Cooke laid much emphasis on the steady loss of life resulting from want of further resolute surgery when obstruction followed an abdominal operation This was due to a faulty conception of what was going on inside or to want of sufficient humility and courage to say that another operation was necessary because something had gone wrong the abuse of various suction tubes with the support of intravenous therapy too often gave rise to a false sense of security We talked of paralytic ileus, when we should be operating for mechanical obstruction

For twenty years Mr Cooke had been urging wider exploration in cases of very advanced abdominal neoplasm It was astonishing what could be accomplished enopause. In Sheldon's (1935) series the 277 male ases were fairly evenly spread on either side of the peak ncidence at 45–50 years; only 2 of his 14 female cases occurred before this age. He has since stated (Sheldon 1951) that 1 of his 2 young female cases did not have proven hæmochromatosis and was included in his chart of the age-incidence in error; hence of his 13 female patients only 1 developed the disease before the menopause.

In view of the small number of women in Sheldon's series I have investigated the age-incidence of a further 202 male and 20 female cases published since 1935.* Table I and the accompanying figure show the age-distribution of these patients (at the time of diagnosis when this is stated) and of Sheldon's patients. In the present series too the male cases were much more evenly spread throughout the adult years of life than the female cases, only 2 of the women being under 45 years of age. It is of particular interest that 1 of these 2 young women, whose case was reported by Murray-Lyon (1936), had had amenorrhœa for thirteen years before dying of hæmochromatosis at the age of 34.

TABLE I—AGE AND SEX DISTRIBUTION OF 512 CASES OF HÆMOCHROMATOSIS

Cases	Age-group (yr.)											
	10–20	21–25	26–30	31–35	36–40	41–45	46–50	51–55	56–60	61–65	66–70	71–75
Males:												
Sheldon (1935) ..	..	2	7	13	37	48	59	56	34	9	8	4

* In the list of references the papers reporting these cases are marked with an asterisk.

who emphasised the synthetic functioning of the mind and students of neurology and endocrinology, who showed the mechanisms linking mental activity with muscular or glandular responses, also contributed to the synthetic outlook Freud drew attention to hysteria as a symbolic response Gradually, too, it became clear that the vegetative neurosis, innervated by the autonomic, is the organism's physiological response to chronic or recurrent emotional states, and there is evidence of affinity between certain emotional conflicts and certain bodily tissues

Dr Alexander relates his outlook to various types of disease—gastro-intestinal, respiratory, cardiovascular, skin, metabolic, and endocrine, and disorders of the joints and musculature Disturbances of the sexual functions are discussed by Dr Therese Benedek There is a brief concluding chapter on therapy The book is clearly and sensibly written, and has a useful bibliography and indexes

Trichlorethylene Anæsthesia

GORDON OSTLERE, M A , M B Camb , D A , deputy first assistant, Nuffield department of anæsthetics, University of Oxford Edinburgh E & S Livingstone 1953 Pp 83. 7*s* 6*d*

A SURVEY of an extensive series of references can easily become tedious , but, though Dr Ostlere has scoured the literature of his subject, his book reads pleasantly There are no unnecessary repetitions, yet judicious cross-references reassure the reader that nothing important is being left out

Despite its title, the book includes, very properly, a chapter on analgesia—though it is a little confusing to find here the chief reference to cæsarean section In the same chapter the author misrepresents Seward, whose " requirements " referred to " anæsthetic mixtures suitable for intermittent self-administration " and not to " obstetrical analgesics " generally An impression is given that inhalation analgesia is the only sort available for use by midwives, whereas in fact they are now permitted to use pethidine, regarded by many as the most useful aid of all Of the various obstetric inhalers designed to overcome variability in vapour concentration, the only one described is the Epstein Macintosh, which, as the author admits, was not approved by the Medical Research Council

Though full references are given to dangers and accidents from the use of trichlorethylene, some anæsthetists will think too little has been made of the risks (e g , that of associating adrenaline with it), and the accidents are for the most part dismissed as due to wrong technique On the other hand Dr Ostlere states clearly what he regards as the limitations of this drug, and he gives a full account of its pharmacology

Vocational Services for Psychiatric Clinic Patients

THOMAS A C RENNIE, M D , Cornell University Medical College , MARY F BOZEMAN, Rehabilitation Project, National Association for Mental Health Cambridge, Mass Harvard University Press London Oxford University Press 1952 Pp 100 8*s*

THIS book describes a study of the vocational problems presented by 380 men and women, aged 15–72 attending six different psychiatric outpatient clinics in the United States of America The data have been analysed in an attempt to discover the extent to which such problems are presented by psychiatric outpatients, the vocational services needed to help in the solution of these problems, and the ways in which clinics and employment agencies can best cooperate in the patients' interests The problems are analysed in relation to age, social and educational background, and medical diagnosis Special groups such as school-leavers, university students the physically handicapped, and the aged are discussed Although the *social scene in America is somewhat* different from our own, the similarities are enough to make this study of interest here , but the book might be more simply written, and the modest conclusions presented less elaborately. Those of particular significance for us are the need to evolve better methods of vocational guidance, and to provide more suitable opportunities for employment for the psychiatrically handicapped and for the aged, and the need for closer coöperation between employment agencies and clinics, preferably by personal consultation between all concerned with the welfare of any patient

Visual Anatomy

Thorax and Abdomen SYDNEY M FRIEDMAN, M D , PH D , professor of anatomy, University of British Columbia Springfield, Ill Charles C Thomas Oxford Blackwell Scientific Publications 1952 Pp 203 75*s* 6*d*

THIS is the second volume in Professor Friedman's series dealing with regional anatomy for the student who has already completed a dissection Unofficial trials with the first volume, on the head and neck, seem to show that he is succeeding in his intention, which is " to present briefly and forcefully that Anatomy which is essential for the practice of Medicine " In this volume the approach is again synthetic, starting with the bones and on these building up successive layers of soft tissues , as before, the emphasis is laid on the illustrations, of which there are 91 These illustrations are sufficiently unusual to compel attention, and in many cases their originality of viewpoint and construction is most helpful The accompanying text is clear and concise, and includes a great deal of information shorn of minutiæ Over these minutiæ trouble may of course arise, for there can be many opinions on what constitutes an " essential " detail Professor Friedman includes a brief section on the back and spinal cord, and another on surface anatomy The plan of these books is stimulating, and it is being energetically carried through , we shall look forward to the volume on the limbs when it appears The price, however, seems excessive

---

New and Nonofficial Remedies (Philadelphia and London J B Lippincott 1952 Pp 838 27*s*)—To be admitted to the American pharmaceutical *What's What*, a new and non official remedy must survive a grilling by the council on pharmacy and chemistry of the American Medical Association The rules are formidable, and though the council emphasise that the acceptance of a particular preparation is not to be interpreted as an endorsement or a recommendation, it is hard to read the rules without admiring the drugs that get through and sympathising with those that fail The first part of the book includes monographs on the action and use of accepted preparations , and later on there are details of tests and standards for the drugs for which official standards are not available In small print at the end is a tremendous list of unaccepted products, with references to reports, presumably cautionary, that have been published about them Perhaps the manufacturers of ' Genuine Gluten Flour ' and a brand of nitrogen trichloride (agene) were not too disappointed at the rejection of their products

Diseases of Metabolism *Detailed Methods of Diagnosis and Treatment* (3rd ed Philadelphia and London W B Saunders 1952 Pp 1179 75*s*)—In this old friend, back *from a rejuvenating holiday with Prof Garfield G Duncan,* the editor, and his publishers, the form has not been changed, though some sections have been assigned to new authors and have in consequence been greatly modified or entirely rewritten A welcome chapter has been included on porphyrin metabolism, and the sections on water balance, diabetes, and vitamin disorders have been extensively revised Each chapter, as of old, concludes with a substantial list of original references No book is perfect, and there are some mistakes and omissions in this one , but the original aim was to help *to bridge the gap between the investigator and the practising* physician, and the new edition continues to do that, and to do it well

Recent Advances in Anæsthesia and Analgesia (7th ed London J & A Churchill 1953 Pp 410 30*s*)—The five years since the previous edition have provided *Dr C* Langton Hewer with so much new material that not only has the book increased by nearly 60 pages but the type is smaller and the pages fuller The new material ranges from apparatus and drugs to such new and controversial innovations as anæsthesia with hypotension Dr Langton Hewer *still retains* the habit of freely inserting his own comments These are always helpful though they are becoming noticeably, and perhaps justifiably, *more pungent with each edition* The book still remains one of the best reference sources to anæsthetic literature In future editions the author should perhaps set a narrower interpretation on " recent," for his work will soon be more accurately described as a textbook

SPECIFIC WATER DIURESIS TEST FOR ADRENOCORTICAL INSUFFICIENCY

S. OLEESKY
M.Sc., M.B.Manc., M.R.C.P.
LECTURER IN THERAPEUTICS, UNIVERSITY OF SHEFFIELD

THE diagnosis of adrenocortical insufficiency still resents many difficulties (de Mowbray and Bishop 953). The most useful laboratory aid is considered to e the Kepler test (Robinson, Power, and Kepler 1941). his test can be divided into two parts: the first is an ssessment not only of the ability to have a water diuresis ut also of the changes in diurnal rhythm which may be resent in adrenal deficiency; and the second part is guide to the ability to conserve chloride and to eliminate rea. Thus the test unites the results of many phenomena nd is not an analysis of one particular defect in adrenal leficiency.

The test as generally performed is tedious and comlicated. Often the patient is unable to drink the large olume of water required, and the second part of the est requires a relatively complicated analysis of blood nd urine. As regards the second part of the test, many ases have been published in which the Kepler factor A is igh, with the first part of the test positive—e.g., in 5* out of the 74 cases of Addison's disease of Levy, Power, nd Kepler (1946)—and some observers may then have rroneously excluded adrenal insufficiency. There may lso be false positive and false negative responses to the first part of the test (Levy et al. 1946); in fact in another 9 out of the 74 cases there was a false negative result to the first part of the test.

It is now well established that the failure of water diuresis in adrenal insufficiency due either to hypopituitarism or to Addison's disease can be restored with cortisone (Chalmers and Lewis 1951, Garrod and Burston 1952, Leaf and Mamby 1952, Oleesky and Stanbury 1951, Slessor 1951, Thorn et al. 1951). Relying on this, Soffer and Gabrilove (1952) have proposed a simplified version of the Kepler test. Briefly, after a water load of 1500 ml. the volume of urine produced is measured over the next five hours, and this volume should exceed 800 ml. and in the normal usually lies between 1200 and 1900 ml. If the volume is small, the test is repeated after oral cortisone. In adrenal insufficiency, either primary or secondary to hypopituitarism, the volume of urine produced is small but is increased to normal after oral cortisone.

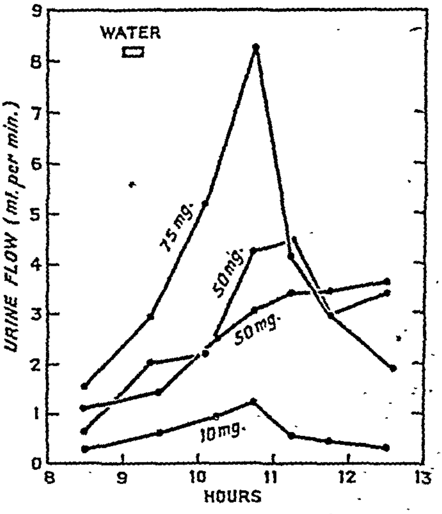
TABLE I—GREATEST RATES OF URINE-FLOW IN PATIENTS WITH ADRENAL DEFICIENCY WITH AND WITHOUT CORTISONE

Case no.	Diagnosis	Controls		Observations after cortisone		
		Volume of water taken (ml.)	Max. rate of urine-flow (ml. per min.)	Dose of cortisone (mg.)	Volume of water taken (ml.)	Max. rate of urine-flow (ml. per min.)
1	Hypopituitarism	1000	1·8	50	1000	13·6
2	,,	1000	1·8	50	1000	10·0
9	,,	900	0·6	50	880	8·7
10[1]	,,	800	0·72	75	870	1·8
14[2]	,,	1000	2·5	50	1000	7·3
16[3]	,,	600	1·2	75	600	8·2
24	,,	800	0·9	75	1000	16·3
3	Addison's disease	1000	0·5	50	920	4·1
18[4]	,,	650	0·73	—	—	—
27	,,	850	2·7	75	850	6·8

1. Patient was a pituitary giant with secondary hypopituitarism, and the dose of cortisone may have been too low, and so only a partial restoration to normal was achieved.
2. Diuresis under cortisone was cut short with intravenous pitressin. Otherwise a greater urine-flow would probably have been reached.
3. Control observation when the patient was on 10 mg. and the second observation when on 75 mg. of intramuscular cortisone daily.
4. Patient ill and died before second part of test could be performed.

AUTHOR'S MODIFICATION

The disadvantages of the test devised by Soffer and Gabrilove (1952) lie in the not infrequent inability, particularly of the adrenal-deficient, to ingest 1500 ml. of water without vomiting, and the fact that each part of the test lasts five hours. A procedure just as simple is for the patient, after overnight deprivation of fluid, to drink as much water as possible up to a total of 1 litre within twenty minutes. The urine-flow is then measured at intervals of fifteen to twenty minutes for two and a half hours. The test can be repeated next day with about the same volume of water, but this time 50–75 mg. of cortisone is given by mouth four hours before the water is taken. The results in any particular case can be reported by recording the maximum rate of urine-flow after taking a particular volume of water, and the maximum rate after the same volume of water but under the influence of a certain amount of cortisone. In adrenal insufficiency the maximum rate of urine-flow will be low—i.e., less than 2 or 3 ml. per minute, and will be restored to normal with cortisone. Table I shows the application of this test to 3 patients with Addison's disease and 7 patients with hypopituitarism. It is well known that treatment with deoxycortone does not affect water diuresis in man and so will not invalidate the results obtained.



A series of water diureses under differing daily doses of cortisone in case 16 with Simmonds's disease. The dose of cortisone is marked on each diuresis curve. The increase in the maximum rate of urine-flow with increasing dose of cortisone is clearly shown.

It is necessary to observe the following precautions:

(1) The patient's serum-sodium level must not be very low, because then even cortisone will fail to produce a normal water diuresis (Garrod and Burston 1952). At one time in case 16, with Simmonds's disease, there was a failure of water diuresis after 100 mg. of oral cortisone, although eosinophil depression had been achieved. At that time the patient's serum-sodium level was only 114 m.eq. per litre and serum-chloride 88 m.eq., though later she had a normal diuresis on 75 mg. of intramuscular cortisone per day, when her serum-sodium was 144 m.eq.

(2) The dose of cortisone must be not less than 50–75 mg., because sometimes a lower dose may fail to restore fully the rate of urine-flow (Thorn et al. 1951). The accompanying figure shows the effect of gradually increasing daily intramuscular doses of cortisone on the water diuresis in case 16. The water load was 600 ml. in each experiment, and each test was made at the same time of the day.

(3) It is essential to use the same time of the day for the control diuresis and the diuresis under cortisone, because the *maximum* rate of urine-flow likely to be achieved varies with the time of day in which the water load is taken (Stanbury and Thomson 1951, Papper and Rosenbaum 1952).

* Levy et al. (1946) state that in 2 of these 5 cases there may have been technical errors.

Readily accepted...

The provision of 'Sulphatriad', the safer sulphonamide preparation, in a form that children find pleasant to take is an important step towards their successful treatment This presentation has the added advantage that dosage can be accurately adjusted to the needs of the patient

'Sulphatriad, because of the decreased risk of crystalluria, is particularly valuable in the treatment of infants, since in these patients the signs of ureteric obstruction such as oliguria may pass unnoticed the palatable suspension provides a convenient method of administering the drug to these patients

'SULPHATRIAD'
trade mark brand
COMPOUND SULPHONAMIDES
SUSPENSION
AN M&B BRAND MEDICAL PRODUCT

MANUFACTURED BY

M&B

MAY & BAKER LTD

SUPPLIES

Sulphatriad Suspension is supplied in bottles of 4 and 40 fl oz (each 3 6 c c (1 teaspoonful) contains sulphathiazole 0 185 Gm sulphadiazine 0 185 Gm and sulphamerazine 0 13 Gm)

We shall be glad to send detailed literature on request

MA322a

PHARMACEUTICAL SPECIALITIES (MAY & BAKER) LTD DAGENHAM treatment. The pathological fracture healed. In 1950 the patient had a pathological fracture of the superior ramus of the right pubis. A second course of deep radiotherapy 2000r. had no effect on the mediastinal tumour, but the pathological fracture of the pubis healed.

In March, 1951, she was admitted to hospital complaining of drowsiness, epigastric pain, nausea, and severe vomiting. For the last few years she had been suffering almost continuously from generalised aching pain, and for the last ten months she had had epigastric pain, which was brought on by food but not relieved by alkalis.

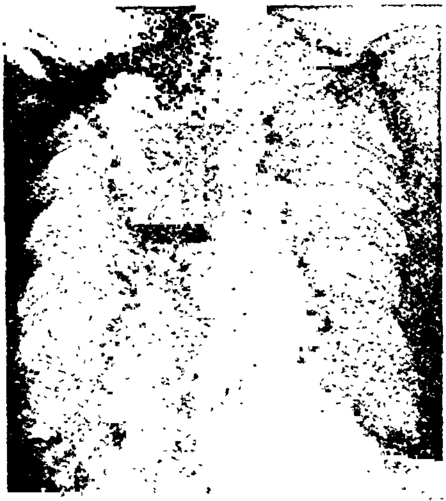

Fig. 1—Dense opacity with calcified rim in right upper mediastinum.

Investigations.—The cardiovascular system showed no abnormality except an extremely low blood-pressure. There were râles at both bases of the lungs. There was no palpable mass in the abdomen, but there was tenderness on pressure in the epigastrium. Plain radiography of the abdomen showed no fluid level and no evidence of intestinal obstruction. A few calcified shadows were seen in the region of the right kidney. A barium meal revealed an ulcer crater above the incisura angularis of the stomach. The duodenal bulb was deformed and showed an ulcer niche at its medial fornix. There was no delay in emptying of the stomach. Films taken in the right oblique position revealed much calcification of the abdominal aorta. A chest radiograph (fig. 1) showed a dense well-defined round shadow, as large as a big plum, with a rim of linear calcification. The trachea below the sternum was displaced to the left. A lateral view showed the tumour to be in the posterior mediastinum. Radiography of the skeleton revealed general osteoporosis; fibrocystic changes in the right humerus, with expansion and thinning of the cortex (fig. 2); fibrocystic changes in the right superior ramus of the ischium and pubis, with healed pathological fracture; and a moth-eaten appearance of the skull, and osteoporosis of the facial bones in contrast to the teeth, which were of normal density, but laminæ duræ were absent (fig. 3). A fractional test-meal showed achlorhydria with histamine response. The urine was acid and contained albumin and leucocytes. A blood-count showed red cells 4,590,000 per c.mm., Hb 94%, white cells 10,000 per c.mm. (polymorphs 89·5%, eosinophils 1%, monocytes 2%, lymphocytes 7·5%). The erythrocyte-sedimentation rate (Wintrobe) was 24 mm. at 1 hour. The blood-urea was 312 mg. per 100 ml., serum-calcium (repeated examinations) 22 mg. per 100 ml., the plasma-inorganic phosphate 2·5 mg. per 100 ml., and the plasma-alkaline phosphatase 17·5 King-Armstrong units.

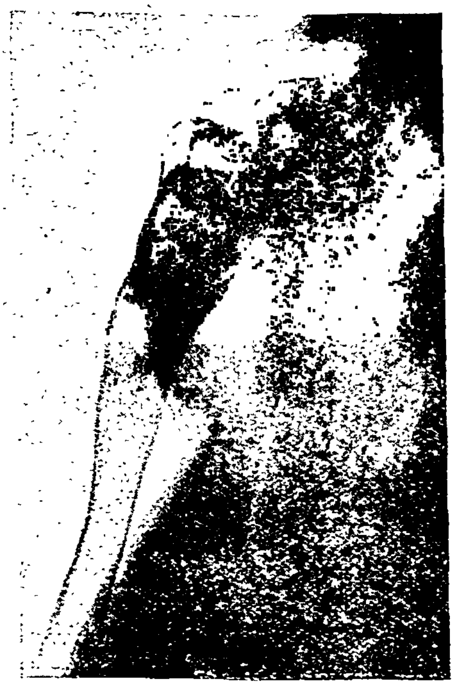

Fig. 2—Fibrocystic changes of proximal half of right humerus, with expansion and thinning of cortex and healed pathological fracture.

Treatment and Progress.—The patient's condition improved with stomach aspiration and intravenous saline solution, and she became more alert. Her blood-urea fell to 88 mg. Operation for parathyroid tumour was advised, but the patient refused and, against medical advice, she was taken home, where she died a few weeks later.

DISCUSSION

It is reasonable to assume that the multiple renal calculi found ten years earlier were due to hyperparathyroidism. Nephrolithiasis and nephrocalcinosis are common and dangerous complications of this condition: they may be present without any recognisable changes in the skeleton, or there may only be general osteoporosis without fibrocystic changes in the bones. The presence of multiple renal calculi should suggest hyperparathyroidism. Investigation of the blood chemistry in these cases should not be confined to estimation of blood-urea but ought to include examination of the calcium metabolism.

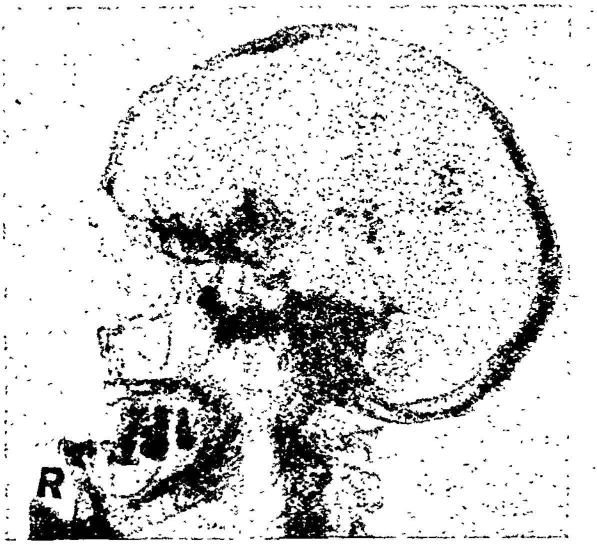

Fig. 3—Moth-eaten appearance of skull and osteoporosis of facial bones in contrast to teeth, which show no decalcification but absence of laminæ duræ, a sign of generalised decalcification.

The second stage of the patient's illness was dominated by involvement of the skeletal system, with pain in joints and bones and with pathological fractures. The clinical notes suggested that failure to recognise the bone lesions as a manifestation of hyperparathyroidism was probably due to the fact that the large tumour in the upper mediastinum had been mistaken for a malignant new growth. Indeed, most parathyroid tumours reported are small. However, Hunter and Turnbull (1931) published a case in which two parathyroid tumours were found, the larger one measuring 7·5 × 5·1 × 1·8 cm. and weighing 26·2 g., and Beyerinck (1932) reported a case in which three parathyroid tumours were found at necropsy, one of them being as large as a hen's egg. The location of parathyroid tumours in the upper mediastinum is not uncommon. Albright and Reifenstein (1948), reviewing 60 cases of hyperparathyroidism, found immune response will no doubt be answered in due course

Although this news sounds very hopeful, there are two points which should discourage over-optimism Firstly, a big effort has clearly been needed to prepare and test enough vaccine for quite a small number of people Each batch of vaccine will need rigorous tests before it can be safely used, and it may be some time therefore before these vaccines are available in any quantity Secondly, though some immunologists believe that the development of resistance to infection and the presence in the serum of antibody to the infecting agent (so often found in close association with one another) are in fact indissolubly linked, this has yet to be proved in poliomyelitis The low prevalence of paralytic poliomyelitis in the community means that very large numbers of people must be immunised before it can be confidently concluded that a vaccine not only produces an antibody response but also protects against paralysis

Radiology in Duodenal Ulceration

THE only satisfactory way of establishing the presence of a duodenal ulcer, other than by laparotomy, is by the radiographic demonstration of unmistakable changes These changes are usually limited to the first part of the duodenum, though they may occasionally be found in the second part[1] The radiographic evidence may be conclusive, when an ulcer crater is seen, inferential, when the duodenal cap is deformed but no ulcer crater is recognisable, or indirect and equivocal, when irritability of the duodenal cap, pylorospasm, radiographic evidence of "gastritis", or other unconvincing signs are present Only the conclusive and the inferential radiographic signs point with a high degree of probability to the presence of an ulcer Radiography, though revealing an ulcer may not reveal an unsuspected cause—for example, a pancreatic neoplasm Clearly radiographic examination is most useful as a check on medical treatment in cases where a crater has previously been seen It must be remembered, however, that duodenal ulcers are often multiple STURTEVANT and SHAPIRO[2] reported finding twenty-five ulcers in one case at necropsy, yet more than two craters are rarely recognised radiographically Thus a patient's symptoms may continue after the healing of an observed ulcer crater, because of the persistence of another ulcer, unrecognised radiographically

At the Royal Society of Medicine on March 20, Dr GEORGE SIMON and Dr G H DU BOULAY reported that, following stringent criteria, they satisfied themselves that an ulcer crater was present in 47% of 134 consecutive patients with clinical and radiographic evidence of duodenal ulceration They pointed out that mistaken identification of a crater may be followed by operation at which a supposed crater is found, and this may be a false confirmation of an inaccurate radiographic observation They examined their patients repeatedly for six months from the first examination In 38 of their 63 cases where an ulcer was present the crater size changed in parallel with the symptoms, but in others symptoms persisted despite apparent healing of the ulcer, or else the size of the ulcer remained the same though symptoms were relieved—in 1 instance symptoms disappeared but the ulcer crater became larger In the 71 cases where they demonstrated no ulcer crater at any examination, no association could be established between alterations in the shape of the deformed duodenal cap and relief or exacerbation of symptoms Their observations led them to doubt whether, once the patient has gained clinical relief, further radiographic examination is useful, for, even though this may show an ulcer crater, it is questionable whether further strict treatment is worth while With duodenal ulceration, radiography, they declared, is primarily a diagnostic procedure, but a further examination is justified possibly after treatment has relieved symptoms, and certainly if the pattern of symptoms changes Preoperative radiography they suggested, is of little value Mr HAROLD EDWARDS, as a surgeon, was concerned to see whether a patient had earned the right to an operation Structural change, not the presence of an ulcer, was the important factor in the decision From experience at operation he doubted whether radiological opinion on the presence of an ulcer crater was completely reliable Patients with duodenal ulcer do not as a rule come to the radiologist until symptoms have been present for some time, and possibly the duration has some influence on healing Dr F PYGOTT said that in a series of 104 cases observed for fifteen months he had observed healing in 17% of cases where symptoms had been present for less than 3 years, in 7% of cases where symptoms had been present for 3–10 years, and in none where symptoms had been present for more than 10 years

It would seem that little or nothing is to be gained by routine radiographic control of medical treatment of duodenal ulceration The main value of radiography is in diagnosis, in the detection of complications, and in the exclusion of a second lesion arising independently In selected cases occasional examinations after clinical cure, or after relapse has been controlled, may be justified, but the results must be interpreted with reserve A general policy on these lines would greatly alleviate the heavy pressure on radiology departments, and would enable more useful work to be done without detriment to the patient

Uterine Cancer and Vaginal Smears

THOUGH malignant cells had been detected in vaginal smears by PAPANICOLAOU[1] as long ago as 1928, the routine examination of smears as a means of recognising early or recurrent uterine cancer was not seriously proposed as a diagnostic aid until 1941 Since then a great deal of work has been done, and there is much evidence on which to base a judgment of the method

Superficial epithelial cells in the female genital tract are subject to cyclical changes and constant exfoliation, which is particularly evident when the cells are malignant and are therefore dividing rapidly In such cases, normal and abnormal cells, shed mainly from vaginal epithelium cervix, and uterine body with an occasional cell from fallopian tubes and ovaries, accumulate in the vagina, and they can be

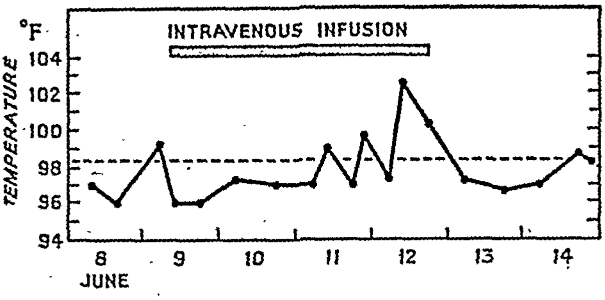

Fig. 2—Treatment and temperature-chart of case 2.

episode of anuria, which had come on after a period of hypotension during an ophthalmic operation. Over each twenty-four hours the patient received 1 litre of Hartmann's solution with 5% dextrose, followed by 1 litre of physiological saline solution with 5% dextrose, and then by 1 litre of 5% dextrose. On the third day she developed a temperature of 100·6°F, which rose to 102·6°F on the fourth day. On this day the infusion apparatus was taken down, after which the temperature settled rapidly (fig. 2).

Investigation.—A drop of Hartmann's solution with 5% dextrose from both the tubing and the bottle was cultured immediately after the drip had been stopped. The bottle, which had just been started, was sterile, but the fluid from the tubing gave a heavy growth of a coliform bacillus.

It grew both at room-temperature and at 37°C, but better at 37°C. It was actively motile. Dextrose, lactose, saccharose, maltose, mannitol, and dulcitol were fermented, with formation of acid and gas. Indole was not produced. The methyl-red and Voges-Proskauer tests were negative. Growth took place in Koser's citrate.

The organism was therefore an atypical member of the coliform group.

No flaws or clots were found in the tubing.

TABLE I—ANALYSIS OF 32 INTRAVENOUS INFUSIONS INVESTIGATED

Infusion fluid	No. of infusions cultured	
	Duration of infusion less than 48 hr.	Duration of infusion 2–4 days
Physiological [illegible]	8	1
[illegible] % dextrose	..	2
[illegible] xtrose	6	6
5% Dextrose	5	4

FURTHER OBSERVATIONS

In view of these findings an attempt was made to determine whether similar but less heavy, and therefore perhaps undetected, infection of infusion fluids occurred at all frequently in hospital practice. The infusion fluids being administered to 32 patients were investigated. The fluid from the tubing was cultured within forty-eight hours of starting the infusion in 19 cases, and from two to four days in 13 cases. The nature of the fluids cultured is shown in table I.

All 32 fluids were found to be sterile.

We then sought to ascertain whether coliform bacilli introduced into infusion fluids could multiply to an extent sufficient to perpetuate the contamination in the apparatus, even though a fresh uninfected bottle was substituted for a contaminated one. All the experiments were made at summer room-temperature (about 20°C). The organisms used were the coliform bacilli isolated from cases 1 and 2.

First it was necessary to determine whether the bacilli multiplied in four different commonly used infusion fluids at room-temperature.

5 ml. of a broth culture, incubated overnight with the organism to be tested, was centrifuged, washed twice in 20 ml. of sterile distilled water, and resuspended in 20 ml. of sterile distilled water. A standard drop (0·02 ml.) was added to a sterile container holding 20 ml. of the infusion fluid to be investigated. This bottle was shaken well and allowed to stand at room-temperature for twenty-four hours. The approximate numbers of live organisms in the infusion fluid were determined by the method of Miles et al. (1938) both directly after mixing at the beginning of the experiment and after twenty-four hours.

The results of typical experiments are shown in table II, which shows that growth took place in physiological saline solution and in Hartmann's fluid with 5% dextrose, but not in 5% dextrose or in physiological saline solution with 5% dextrose. A possible explanation for this was suggested to us by the fact that Bolton Carter et al. (1952) found that the mean pH of all the bottles of dextrose solution examined by them was 4·5. Using Gillespie's method for unbuffered solutions (cited by Fildes 1931) we determined the pH of three samples of each of the four infusion fluids, and the mean results were as follows:

TABLE II—RESULTS OF INFECTING INFUSION FLUIDS

Infusion fluid	No. of living coliform bacilli per ml.			
	From case 1		From case 2	
	At 0 hr.	At 24 hr.	At 0 hr.	At 24 hr.
Physiological saline ..	55,000	650,000	28,500	285,000
Physiological saline with 5% dextrose	45,000	20,000	28,500	Less than 5000
Hartmann's fluid with 5% dextrose	125,000	450,000	22,000	1,900,000
5% Dextrose	65,000	50,000	42,500	Less than 5000

Fluid	*Mean pH*
Physiological saline solution	6·3
Physiological saline solution with 5% dextrose	4·3
Hartmann's solution with 5% dextrose ..	6·1
5% Dextrose	4·1

The pH of the two solutions in which coliform bacilli multiplied was thus near neutrality. Evidently dextrose solutions become acid when sterilised and do not support growth. Hartmann's solution with 5% dextrose has a pH near that of physiological saline solution and allows growth. The acid produced from dextrose is apparently neutralised by the sodium lactate in Hartmann's solution.

The next step was to determine whether the coliform bacilli isolated from our two cases could multiply in the running fluid of an infusion apparatus under conditions similar to those of intravenous therapy.

Small volumes ranging from 1 drop to 1 ml. of a suspension containing a known number of coliform bacilli, washed as before, were introduced into a fresh litre bottle of infusion fluid. A sterile giving set with rubber tubing and needle was attached to the infusion bottle. The needle was passed

TABLE III—RESULTS OF EXPERIMENTS IMITATING INFUSION CONDITIONS

Organism	Infusion fluid	No. of organisms introduced into first litre bottle	Organisms per ml. after				
			0 hr.	1 day	2 days	3 days	4 days
From case 1	Physiological saline solution	1,500,000	1500	35,000	160,000	1,500,000	..
From case 1	Physiological saline solution	10	0	0	About 1	10	80
From case 2	Hartmann's solution with 5% dextrose	600,000	600	2500	5,000,000	Very large numbers	..
From case 2	Hartmann's solution with 5% dextrose	250	0	0	About 1	1000	..
From case 1	5% Dextrose	6000	6	0	0	0	..

number of principals increased by some 500 Fresh admissions to lists totalled 1566, of which 1177 were for replacement of doctors who had died or retired 781 doctors were admitted to partnerships in established practices, and, of these, 344 had served preliminary assistantships During the last three years rather less than one-fifth of the total of assistants have become partners, but the evidence suggests that this proportion is increasing as a result of the Danckwerts award At first sight these figures are encouraging, but several questions must be answered before the chances of the more recently qualified can be estimated We do not know, for instance, how many mature doctors, including senior registrars who have been unable to attain consultant status, are still trying to enter general practice, but the total is likely to increase in the coming months, as Dr FORRESTER and Dr WALTON make clear in a letter on p 793 Nor do we know how many replacements can be expected in future—the number was rather smaller last year than the year before An actuarial forecast would be helpful. The increasing rate of admission of assistants to partnerships is on the whole satisfactory, but the fall of 150 in their total suggests that its effect may be to improve the status of those already practising without increasing the opportunities of entry for younger men Certainly advertised assistantships, even in some of the less attractive areas, continue to draw an excessive number of applications The formation last year of over 300 new practices in under-doctored areas is welcome, but such expansion will obviously be limited, and there are already signs of a better distribution of doctors, the number with either very large or very small lists is tending to decrease At the top of the scale, last year there were 7397 practitioners with average lists of 2869, whereas the year before there were 7055 with average lists of 3009 At the other end of the scale, last year there were 1062 practitioners with average lists of 2010, as against 1075 with average lists of 1941 in the previous year

Recruitment to medicine is governed by the demand for doctors and the capacity of the medical schools After the late war the demand seemed to be inexhaustible and the numbers qualifying increased but the position has changed, and now the profession is probably becoming overcrowded The Medical Practices Committee emphasises the difficulties of attempting to predict future requirements of doctors in the present changing situation Nevertheless the attempt should be made The medical curriculum lasts more than five years, if the schools are accepting too many students they should know as soon as possible From the professional standpoint the health service ought to provide a reasonable chance of a permanent post, without undue competition, for a doctor as soon as he is experienced enough to fill it, too long in temporary or junior posts is not good for the doctor or for the service The status of principal should be generally attainable in general practice between the ages of 30 and 35, and that of consultant a year or two later Last year the average age of successful applicants in general practice was 36 This is better than the average of 38 in the previous year but there are still doctors over the age of 40 who are finding entry extremely difficult Oddly enough there are still too few applicants for junior posts as house officers, senior house officers and registrars in the peripheral hospitals This is partly due to an absolute shortage, but it also to some extent reflects unequal distribution The compulsory preregistration year in hospital may improve the supply of house officers, but it can hardly affect the slightly senior posts Doctors might be glad of a year or more as registrar in a peripheral hospital if their future seemed more assured than it is now, and if they were convinced that, when they applied for a post in general practice, registrar experience would be counted an added qualification and not, as FORRESTER and WALTON assert, "usually a positive disadvantage An improvement at the top would undoubtedly ease the situation lower down the ladder

MEASLES IN VIRGIN SOIL

MOST of us have heard of epidemics of measles which decimated the populations of remote islands or other *isolated communities from which the disease had been* absent for well over a generation There are records of very high mortality in such outbreaks among the native population of the Amazon (1749), Esthonia (1820), Hudson Bay Indians (1846), the Cape Hottentots (1852), Tasmania (1854), and Mauritius (1874) In Fiji in 1875 about 20,000 people—nearly 25% of the population—died of measles[1], and in the next outbreak 32 years later 6% of the population died In the Faeroe Islands, after a great epidemic in 1781 there was no measles until 1846 when about 6000 (78%) of the 7782 inhabitants contracted the disease, none of the 98 old persons who had had the disease in 1781 had a second attack

For the first time in medical history, measles gained a foothold in Southern Greenland in April, 1951[2] The source of infection was a young Greenlander, infected in Copenhagen, who, soon after landing in Greenland and just about the time of onset of symptoms, took part in a public dance attended by 200–300 people from all parts of the community This outbreak is certain to become a classic in medical history because of the extremely high attack-rate The number of persons who contracted typical measles within three months was 4221, a further 36 had less definite attacks 31 who had previously had measles in Denmark, and 27 treated prophylactically with convalescent serum or gamma globulin did not contract the disease In the Julianehåb district, to which the disease was localised, of the whole unprotected population of 4262 only 5 escaped the disease, this gives an attack rate of 999 per 1000—surely a record The mortality was much lower than might have been expected, probably owing to penicillin treatment of complications combined with the modification produced by sero prophylaxis of about 1000 people both of which measures were rapidly organised from Denmark Only 77 deaths were recorded—a rate of 18 per 1000

The incubation period was nearly always 13–14 days from rash to rash, but in 1 case it was certainly as long as 19 days, and in several it was only 6–10 days The course of the disease was remarkable only for two special features a very pronounced enanthem, usually hæmorrhagic of the mouth and palate present in 75% of the patients in the prodromal stage, and virtual absence of conjunctivitis, photophobia, and eye complications These may be related respectively to the Greenlanders' well known tendency to hæmorrhages and to the Northern climate The frequency of complications in a series of 1657 patients who were not treated prophylactically was 15% and of these complications 80%

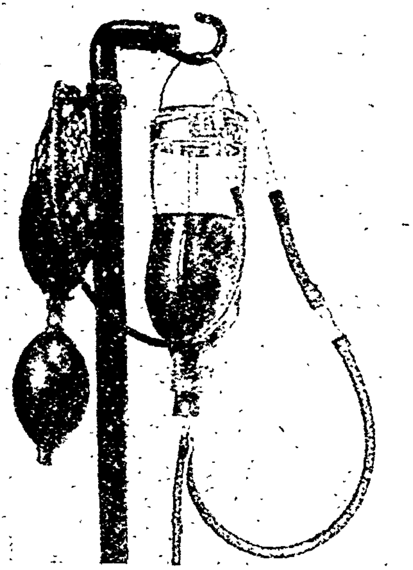
if the exposure was big enough, and if enough time and care were given to the operation, which should be as gentle and bloodless as it was courageous and ruthless.

Mr. Cooke mentioned the inflammatory factor in malignant disease—particularly of the colon. An "impossible" case might become a relatively easy problem after a short-circuit or colostomy. After a time most of the bulk and fixity of the mass might resolve, and the residual malignant mass could be dealt with by a reasonable operation. Re-exploration might then be well worth while.

New Inventions

AN AIR FILTER FOR PRESSURE TRANSFUSIONS

DURING investigation of cases of unexplained pyrexia following transfusion the possibility of introducing infection through the bellows used to apply air-pressure was studied. Though it is generally recognised that the use of positive air-pressure carries risks and requires direct medical supervision, we had not previously considered the hazard of infection. We have found that the bellows used for this purpose almost always become contaminated with small quantities of blood or other transfusion fluid which readily flows back through the air-intake tube of the standard giving set. The rubber bellows are difficult to sterilise and, being opaque, do not reveal the contamination which may exist inside them. Several such bellows after use were blown out over 6% agar plates, and in each case there was a heavy growth of bacteria, including *Pseudomonas pyocyanea* and gram-negative and gram-positive cocci.



To obviate the risk of infection of the transfusion fluid a simple cotton-wool filter was devised which consists of a glass U-tube containing a wad of dry cotton-wool in each arm. One arm is connected to the air-inlet tube of the giving set by about 18 in. of rubber tubing. A short length of glass tubing with a constriction is inserted in the rubber tubing about 3 in. from the U-tube to prevent the cotton-wool from being blown into the transfusion bottle. The U-tube hooks over the wire support of the bottle-holder, and the bellows are attached to the open end, the whole thus being conveniently supported without danger of kinking. The glass tubing and rubber tubing are cleaned after use, new pieces of cotton-wool are inserted, and the whole is sterilised at 5 lb. pressure for 15 minutes in a tin similar to that used for giving sets. In attaching the filter to the bottle it is important to hook the glass U-tube on to the support before attaching the rubber tubing. This prevents flow-back of the blood under gravity from the air-inlet tube of the giving set.

These filters have been tested with bellows known to be contaminated, and they prevent the passage of organisms; their regular use over the past year at this hospital has shown them to be convenient and acceptable in practice.

Reviews of Books

Influenza and Other Virus Infections of the Respiratory Tract

C. H. STUART-HARRIS, M.D. Lond., F.R.C.P., professor of medicine, University of Sheffield. London: Edward Arnold. 1953. Pp. 235. 30*s*.

IN the winter months the general practitioner spends much of his time in dealing with diseases of the respiratory tract, and particularly with the heterogeneous group of acute infections caused by filterable viruses. Professor Stuart-Harris has for many years been concerned with the delineation of clinical entities from the general run of "flu's" and "virus pneumonias," and, having graduated to a chair in clinical medicine via bacteriology and virology, he is well placed to consider these infections from both the clinical and the laboratory viewpoints. He has now condensed the results of many years' inquiries into a readable book which should commend itself to all who are interested in respiratory diseases. Influenza receives the most detailed treatment, but there are chapters on febrile catarrh, the common cold, atypical pneumonia, psittacosis and ornithosis, and Q fever. Each infection is considered in its clinical and epidemiological aspects along with descriptions of the pathology, laboratory diagnosis, and treatment. Throughout, Professor Stuart-Harris tries to avoid accepted textbook patterns of description and to write from his own experience, and the book contains much valuable and previously unpublished material. There are numerous X-ray films and photographs of histological material, and the text is well supplemented with figures and charts.

Biochemistry of Gastric Acid Secretion

EDWARD J. CONWAY, M.D., D SC., F.R.S., professor of biochemistry and pharmacology, University College, Dublin. Oxford: Blackwell Scientific Publications. 1953. Pp. 185. 47*s*. 6*d*.

Professor Conway's monograph on the mechanism of gastric acid secretion presupposes an intimate knowledge of the biochemistry of cellular secretion. It is thus of limited appeal; but it will be of particular interest to the biochemist and physiologist. Some of the reasoning is difficult to grasp at a first reading, and much of the subject matter is highly technical.

Dr. Conway draws an interesting parallel between the secretion of succinic acid by the yeast cell and the hydrochloric-acid secretion of the oxyntic cell of the gastric mucosa. The bulk of his monograph he has given over to a discussion of the redox-hydrogen ions, while under the heading of energetics he describes the energy changes involved in the redox cycle and the sources of energy consumed in cellular secretion and osmotic work. In a short final section he considers the significance of gastric urease in the human subject in relation to the neutralisation of gastric acidity and mucosal protection, and he gives an outline of the urea therapy for peptic ulceration. Unfortunately, he does not offer enough data about the 79 patients he has treated to allow the reader to judge of the value of the method.

Psychosomatic Medicine

Its Principles and Applications. FRANZ ALEXANDER, M.D., director, Chicago Institute for Psychoanalysis, clinical professor of psychiatry, University of Illinois. London: Allen & Unwin. 1952. Pp. 300. 21*s*.

Dr. Alexander has contributed much to the development of the psychosomatic approach, and his new book is a useful account of the underlying theory and practical therapeutic results in this field.

He describes the mechanistic "analytic" medical theories of the 19th century, which still exert undue—and largely unrecognised—influence. The new "synthetic" viewpoint first appears in the work of Kahlbaum, Wernicke, and Babinski and in the brilliant observations of Kraepelin. The discovery by Noguchi of the spirochæte in the brains of patients with general paralysis, and the results obtained by Horsley from thyroid transplantation in myxœdema, helped to convince clinicians that mind and body had mutual interactions; while in the study of the neuroses Freud's method of psycho-analysis, and his theory of ætiology, introduced scientific method to what had been a welter of unrelated observations. Members of the *Gestalt* school of psychology, is relatively acid, is less likely to support bacterial growth than normal saline or Hartmann's fluid with 5% glucose; but their finding is none the less important.

On page 775 Dr Bull and Mr Hurst report that they investigated cases of unexplained pyrexia after transfusion, and they give evidence that accidental infection is a possible hazard of transfusions assisted by air-pressure. Apparently the bellows of a pressure transfusion apparatus regularly become contaminated with small quantities of transfusion fluid, and this permits the growth of a variety of bacterial species including *Pseudomonas pyocyanea*. Bull and Hurst describe a simple device which prevents infection from this source by filtering the air from the bellows through a U-tube containing a wad of dry cotton-wool in each arm.

These different reports clearly emphasise that various forms of treatment as now administered in the wards of hospitals need to be carefully overhauled, because there is little doubt that some of them constitute potentially dangerous sources of infection. The first requirement of any treatment is that it should not do harm, and it is a grave reflection on all concerned when accidental infections in hospital cause avoidable suffering and even loss of life. Because of our increased control over many common infections there is a possible risk that we may grow forgetful and perhaps even contemptuous of bacteria.

DOCTOR AND CAMERA

PHOTOGRAPHY has been used in medicine for more than a century; but only in recent years have we begun to appreciate how much the camera can help us. An exhibition this month at the Royal Photographic Society's house in Kensington surveys the century's progress and makes it clear that this has been most rapid in the past fifteen years. For instance, close-up pictures of the eye, and colour photography of the living retina with snapshot exposures, have only been satisfactorily achieved since 1939. Techniques for endovesical and intraperitoneal photography are post-war developments, exemplified in a fine colour print of a nodule of regenerating tissue on the surface of a living syphilitic liver.

The main function of photography is simply to record—for example, the changing pattern of skin lesions, the repair of defects by plastic surgery, and the follow-up of a case. The exhibition includes a series of pictures showing a patient in 1905 before removal of his cerebellar tuberculoma, and as he is today, together with pictures of the pathological specimen and its histological section. There is also a panel of smallpox cases with views of the floating hulks on the Thames off Deptford which used to be an isolation hospital, which teaches a good deal of value in public health as well as illustrating a disease that is now uncommon. But photography is also an important research technique. Infra-red pictures will display the invisible subcutaneous venous network; and photogrammetry will record growth and physical type for somatotyping and other anthropometric studies.

As the techniques have grown so have the numbers of specialists, and now over 300 medical photographers belong to the Royal Photographic Society's medical group, which was founded in 1946. There are, however, still many hospitals and many doctors, even in research departments, who have no inkling of what the medical photographer can do to help them. The present excellent little exhibition is composed largely of portable panels, and could go on tour to medical schools. Perhaps the organisers will consider how they can circulate their show, if only in part. Photography is a part of the Science of Light, and should not be hidden under a bushel.

DESERTED CHILDREN IN FRANCE

IN France the task of saving and rearing children deserted by their parents, begun in the 17th century by St Vincent de Paul, has been faithfully pursued by later generations. His plan of placing the newly born with country foster-parents is still sound; and, though the infant mortality among these foundlings was at first very high, the centuries have seen a steady improvement. Marcel Lelong[1] notes that of 55,000 newborn children saved between 1790 and 1802, some 31,000 died. Up to 1862, when receiving centres were set up, children were still being left on the turntables set in monastery doors for the purpose. In 1874 medical supervision of foster children was started and in 1926, in the Département de la Seine, the *Pouponnière d'adoption*—giving the newly born residential care in a crèche—was established, working in conjunction with the centres for approved wet-nurses. In this department the neonatal mortality among children in the care of the Assistance Publique (A.P.) is now lower than the average for the country as a whole.

The numbers of deserted children coming under the care of the Seine A.P. have fallen considerably in the course of time (from 7676 in 1772, to 5026 in 1900, 3477 in 1920, and 758 in 1946); but a change—presenting serious problems—has taken place in the age range of children deserted. In 1900 more than half the children were under the age of 3 months, and two-thirds of them under the age of 2 years; in 1949 only about 5% were under 3 months, nearly half were over the age of 6 years, and some 15% over 14. Concurrently, the numbers of children confided temporarily to the care of the A.P. have risen steeply—from 3307 in 1880 to nearly 12,000 in 1952. This has been partly due to a humane interpretation of regulations: the A.P. will accept children brought in at any hour of the day or night. Not all of them come from the Seine area—some are from overseas, from distant or neighbouring departments, or from other European countries, and many of them are children of refugees or displaced persons passing through Paris. About 70% belong to normal families temporarily in difficulties and unable to look after them, and these children usually rejoin their parents within three weeks.

The decline in the numbers of babies under 3 months is said to be leading to a gradual disappearance of would-be adopters. Many of the older children have been profoundly affected by their experiences, which often include a broken home, immoral or delinquent parents, and sometimes a personal experience of sexual assault or incest. Small wonder that they are often abnormal—vagabonds, potential delinquents, or at the very least socially maladjusted. Children with such a background, as we know from our own experience, are not reclaimed in a moment; but many of them do respond to sympathetic handling in secure surroundings. But French children of this kind suffer a further devastating blow. As soon as the A.P. undertakes their permanent care, a process is started to secure their legal separation from their parents. Months pass before the judgment is given, and even when it has been passed the parents retain the right for three years to ask that it shall be reconsidered. The whole process is extremely painful and damaging to any child who is old enough to know he is being cast off or—as he more often imagines it—cut off by tyrannical authorities from parents who want to keep him. Moreover, he is thus artificially made into an orphan at an age when adoption can no longer be expected, and when readjustment is at best difficult to achieve. The older children rebel against the judgment and resent all attempts to place them with foster-parents. They remain a charge on society and ultimately a danger to

"I dread the rustling of the grass"

WILLIAM WORDSWORTH

No sooner has the blossom languished and spring shed her coat of many colours than the tall grasses ripen. The air is again pollen-laden. To those who love the countryside these richly-clothed meadows are a joy: to sufferers from hay-fever they are merely the signal for a fresh period of acute discomfort. Yet there is a solution — BENADRYL, probably the most potent of all histamine antagonists, may be taken just before and during the pollen seasons and, in the majority of cases, provides effective relief.

BENADRYL a successful anti-histamine

Capsules (25 or 50 mg.) in bottles of 50 & 500;
Elixir in bottles of 4 & 16 fl. ozs.

LONDON: SATURDAY, APRIL 18, 1953

Poliomyelitis Vaccines

THERE have lately been important changes in our outlook on the pathogenesis of poliomyelitis, and in this issue Dr. MEENAN describes the basis for the modern concepts of this disease. Epidemiological investigations have established that the paralytic disease, on which attention had earlier been focused, is the exceptional rather than the general result of first contact between patient and virus. The virus is widely distributed throughout the world, and, curiously enough, the more widespread it is in a particular population the smaller the number of paralytic cases. This paradox is explained by the fact that if the first contact with the virus is in infancy paralytic disease is less likely than if the first infection is in adult life. In countries where the general standard of hygiene is poor, most first infections are in infancy, and the population has a high general level of immunity to the virus. In more civilised communities this first meeting with the virus is often postponed until the age at which paralytic disease is a more common result of infection, and, as MEENAN points out, it is we who, by altering our living conditions, have upset the happy balance between virus and man which had earlier prevailed.

We have also changed our ideas about the strict neurotropism of the virus. The strongest evidence that poliomyelitis viruses are not strictly neurotropic has been the discovery by ENDERS et al.[1] that the viruses can multiply in cultures of non-neural tissue maintained in vitro. This discovery opened out an enormous new field in which to study the growth habits of the virus and raised hopes of preparing practical vaccines. Moreover, it supported the view that in its pathogenesis poliomyelitis resembled other virus diseases much more closely than had hitherto been believed. The subsequent news from HORSTMANN [2] and BODIAN [3] that the virus entered the blood-stream in the early stages of experimental poliomyelitis fell on receptive ears. It is not yet clear whether this viræmia, which is believed to be present in human infection as well, is an accidental occurrence or a pointer to the all-important route by which the virus invades the central nervous system from its primary site of infection; but there is no doubt that opinion has swung over to the latter view. If poliomyelitis behaves like other virus diseases, it should be possible therefore to set up an antibody barrier to the spread of virus through the blood-stream and to prevent invasion of the central nervous system. And so a cheerful optimism has replaced the all-pervading pessimism about the chances of preventing paralytic poliomyelitis.

The first indication that these theoretical possibilities might work in practice came from a trial [4] in which it was shown that gamma-globulin given to large numbers of children caused a significant reduction in the prevalence of paralytic poliomyelitis. But active immunisation is obviously the only practical proposition, and here there are two clearly divided schools of thought. The first favours immunisation with live attenuated virus, and its members can cite smallpox, yellow fever, and more recently rabies, as strong arguments to support their view. The second and more cautious school prefers the use of inactivated vaccines whose safety, it is said, would outweigh the disadvantages of difficult and expensive production. Preliminary trials with inactivated vaccines were lately described by HOWE,[5] but these vaccines carry the risk of allergic encephalomyelitis arising from injections of nervous tissue. This danger can best be averted by growing the virus in vitro in non-neural tissues, and the results of trials with vaccines prepared in this way have now been reported. SALK [6] and his colleagues have taken advantage of some recent advances to prepare a vaccine which seems to have considerable promise. Poliomyelitis viruses of the three immunological types [7] were grown in vitro in cultures of monkey kidney and testis. (Monkey tissue was preferred to human because it was more readily available and because the virus of serum-hepatitis might be transmitted by human material.) The tissues were suspended in a chemically defined medium [8] in the absence of serum, amniotic fluid, or other foreign proteins; this medium has lately been shown [9] [10] to maintain the viability of the tissues and to support virus multiplication. Virus grown in these cultures was inactivated by careful treatment with formaldehyde, and it was then shown to be non-infective by intracerebral inoculation of monkeys. These vaccines were then given to 161 persons by one of two techniques: in one series of experiments the aqueous vaccine was inoculated intradermally; in a second series the vaccine was given intramuscularly in a water-in-mineral-oil emulsion, which has an adjuvant effect.[11] The results of these experiments were measured by antibody tests in tissue culture, comparing antibody levels of sera taken before and after vaccination. It is difficult at present to assess fully the value of these results, for although they are described at length, many of the experiments were still in progress at the time the report was written. It is clearly shown, however, that shortly after immunisation with a mixed adjuvant vaccine, containing the three antigenic types of virus, antibody was induced to all three types. Moreover, it seems that the vaccine mixed with adjuvant is, in some cases, a better antigen than the aqueous vaccine. A number of questions on the effect of the preliminary immune status of the subjects and on the duration of the

the W R was negative in all cases Histoplasmin tests were also negative and so was the Kveim test in the three patients on whom it was performed All twenty patients were afebrile during the period of observation In four cases there was enlargement of the peripheral lymph-glands which subsided at the same time as that of the hilar glands Chaves and Abeles emphasise that the probability of spontaneous regression should be kept in mind when deciding what to do Irradiation is seldom justified until the diagnosis has been confirmed, and in particularly difficult cases where the lesion is unilateral, a thoracotomy may be necessary to identify an operable neoplasm It seems probable that many of the unexplained cases are the result of persistence of glandular enlargement due to a subclinical infection which has passed unnoticed

A MIND REGAINED

A SEVERE psychosis may imprison the patient for long periods in an inaccessible world of the mind People who have suffered this experience have written moving accounts of it, and have been at particular pains to show how apt, sane, and reasonable his behaviour seems to the psychotic And well it may, for his aberration lies in the false beliefs on which he is obliged to act not in the responses he is provoked into making to them Not many writers, however have described in detail the experience of recovery the returning interest in the fate of others, and the growing awareness of the hospital—both as a refuge and a place of stress, but also, and above all, as a social community Mr Paul Hackett, an outstandingly good writer, describes in *The Cardboard Giants*[1] this slow and agonising process of return

He was a schizophrenic patient in a veterans' hospital in America—a good hospital, as far as he was concerned, though he outlines a darker picture of the blocks for relapsed or chronic cases He was given able psychiatric care, but there, as here the numbers of the sick limited the time the psychiatrists could devote to individuals The attitude of the patients to their doctors is brilliantly sketched it recalls the response of the multiparous woman to the spinster midwife—a blend of respect for the training and humorous contempt for the ignorance Among these sick men, however, the contempt was sometimes, and inevitably, bitter

Mr Hackett came to recognise and integrate two conflicting trends in his own personality, but he does not believe his illness was purely psychogenic His interest in the physical concomitants of his disorder—particularly the cyanosis of his hands—was roused both by his psychiatrist and by another doctor, a fellow patient, and he willingly collaborated in any shot-in-the-dark measures—such as periods of oxygen breathing and abstention from coffee and cigarettes—which might be expected to reduce his anoxia The episode underlines our ignorance of the basic physiology of mental disorders, and the urgent need for research

NUTRITIONAL RESEARCH IN INDIA

THOUGH he had previously worked on goitre and cretinism, Sir Robert McCarrison's studies of nutritional disease may be said to have begun in early 1918, when he returned to India from active service and was posted to the Pasteur Institute Coonoor Built in 1906, for the production of anti rabies vaccine and the treatment of patients with rabies this institute is situated in the Blue Mountains amid magnificent scenery, and the climate is mild McCarrison occupied an empty room in which he started officially to study beriberi and though his work was twice stopped he twice managed to begin it again Fortunately in 1926 Lord Linlithgow's Royal Commission on Agriculture visited Coonoor, and with its backing he was able to build up the well known Nutrition Research Laboratories which he directed until he retired in 1935 His successor there was W R Aykroyd, now director of the Nutrition Division of the United Nations Food and Agriculture Organisation who held the appointment for ten years and Aykroyd in turn was succeeded by a biochemist V N Patwardhan under whom are clinical and pathological sections under the clinical scientists C Gopalan and V Ramalingaswami

Despite the ideal climate of Coonoor, the situation has had two serious disadvantages for the most important centre of nutritional research in India—it is relatively inaccessible and it has no immediate contact with clinical material Further, although the research laboratories took over the whole of the first floor of the Pasteur Institute and overflowed into a neighbouring jam factory they have had insufficient space The governing body of the Indian Council of Medical Research has accordingly decided that they should be transferred to Hyderabad, and on March 31 the health minister for India, Rajkumari Amrit Kaur, laid the foundation stone of the new buildings In her speech she spoke of the debt India owes McCarrison "India" she said "has particular reason to be proud of his achievements, for it was his foresight and, may I say, genius which made it possible to establish these Laboratories as an institution devoted entirely to the study of nutrition" She emphasised the need for pure nutritional research, and for bringing this into intimate contact with those advancing or practising clinical medicine In Hyderabad the Nutrition Research Laboratories will be closely associated with the hospital and the medical college

Thus a few days after McCarrison celebrated his 75th birthday his distinguished creation enters on a new and enlarged existence It has both a fine record and great opportunities

THE BUDGET

INTRODUCING his second budget last Tuesday, Mr R A Butler spoke with more robust confidence than last year, for the adverse balance of payments has been rectified, and his aim of disinflation has been achieved For the first time since the end of the war no new taxation is proposed, and income-tax is to be reduced by *6d* in the pound and purchase tax by 25% from present levels The provision for food subsidies is about £220 million, compared with £250 million last year, this results from decontrolling eggs and cereals Social services are expected to cost £1264 million—an increase of about £80 million Referring to the committee which is to review the cost of the National Health Service,[1] Mr Butler said "I fail to see why it should be called political cowardice for those of us who intend to maintain the health service to have it impartially examined in order that those who pay for it, whether political or non-political, should get value for money spent"

This budget promises a little relief for nearly everyone, but old age pensioners and others with small incomes may be disturbed by the rising price of their basic foods

demonstrated microscopically in vaginal smears. Many methods for collecting the material from the posterior fornix have been described: PAPANICOLAOU [2] used a curved glass pipette and rubber suction bulb; KRAUSHAAR et al.[3] recommended a damp standard cotton swab protected by a sheath of rubber tubing; and HYAMS [4] described an ingenious "direct contact smear technique." AYRE,[5] on the other hand, maintained that smears taken directly from the external os provided better material for the diagnosis of cervical carcinoma, and he designed a spatula [6] for collecting predesquamated cells from the squamocolumnar junction of the cervix. However the material is obtained, it is spread as a thick smear on a glass slide and immersed immediately in a fixative of equal parts of 95% alcohol and ether. Fixation takes only a few minutes, though the slide can be left in the fixative up to one week without harm. The slides are stained with PAPANICOLAOU's or SHORR's "differential stain." [7 8] But, though the taking of a vaginal smear may be simple enough, the interpretation of the microscopical appearances can be very difficult, even for those with considerable experience in normal and abnormal vaginal cytology. The appearances which suggest a diagnosis of malignancy are the same as those of individual cells in ordinary paraffin sections of malignant tissue. They include pleomorphism with bizarre cell shapes (the so-called tadpole cells), intranuclear changes (an irregular chromatin network and an increase in the chromatin content), variations in the size and shape of the nucleus, atypical mitoses, cells with multiple nucleoli, and excessive cornification. In addition there are the abundant leucocytes, histiocytes, and degenerated red cells characteristic of the infection that is so often present. A diagnosis of cancer can be made with greater confidence when groups of cells, rather than single cells only, are seen. PAPANICOLAOU et al.[9] recommended the following classification:

Class 1.—Abnormal or atypical cells absent.

Class 2.—Atypical cells present, but without abnormal features.

Class 3.—Cells with abnormal features present, but not pathognomonic.

Class 4.—Fair number of pathognomonic cells and cell clusters present.

Class 5.—Large number of conclusive cells and cell clusters present.

Thus, classes 1 and 2 are negative smears, class 3 is suspicious, and classes 4 and 5 are positive.

Much has been written during the past ten years about this method of detecting early carcinoma of the female genital tract, and many gynæcologists have welcomed the method with enthusiasm and advised its routine use. On the other hand, some doubt the accuracy and others the practicability of the procedure as a routine. The shortcomings of the method lie in its expense and in the tremendous time it takes—"some 500 hours of work necessary to reveal one carcinoma" [10]—as well as in the difficulty of securing staff who have sufficient experience of its use. Limitations such as these have restricted its use to the larger teaching centres where adequate funds and skilled staff are available. A further drawback is that at best the diagnosis can only be provisional; and the final answer depends on the examination of material obtained by cervical biopsy or by curettage. Clearly, the vaginal smear can never replace these orthodox biopsy methods. On the credit side, the best that can be said is that by a simple, painless, and harmless procedure an occasional case of clinically unsuspected cancer of the genital tract may be recognised and so treated in good time. Against this would have to be set the mental and physical trauma in borderline cases, eventually found to be free of cancer, during observation which may be prolonged and investigation which may well include cervical biopsy under anæsthesia. There is also the danger that extensive operations may be undertaken unnecessarily. Again, if cancer has been overlooked or develops later, a negative vaginal smear may perhaps give a false sense of security and delay treatment. A sense of proportion is clearly needed. In the years 1939–49, just over 400,000 women died of malignant disease in England and Wales, and of these deaths 48,000 were due to uterine cancer. In the same period, 81,000 women died of carcinoma of the breast, and nearly 27,000 of carcinoma of the rectum. These figures suggest that there is probably a stronger case for establishing routine examination of the breast and rectum in all gynæcological clinics; for in this way the gynæcologist may detect a symptomless cancer, and perhaps save a patient's life, more readily than he would by searching for an elusive cancer cell in vaginal smears.

Too Many Doctors?

SOME time ago we reviewed the rate of entry into the profession and tried to estimate the number of permanent posts required for those qualifying.[1] Since the likely opportunities for consultants were known we were able, by an arbitrary calculation which we believed to be conservative, to show that in England and Wales about 700 openings were required each year in general practice. Some of those who qualify elsewhere in the United Kingdom settle in England and Wales; but for want of precise information these were excluded.

New figures for Scotland [2] fill in a little more of the picture. In Scotland between 550 and 600 doctors are qualifying each year, of whom at present about 230 can expect to find employment at home. These appointments are chiefly for replacement: the rate of expansion in general practice has not been rapid; in the two years up to July, 1952, principals increased by 37 and assistants by 23. A quarter of those attaining principal's posts are over 50 years of age; but calculations based on the ages of those now practising do not encourage hopes of a speedy increase in the openings. If a fair proportion of the 300 surplus Scottish graduates are to find employment as general practitioners in England and Wales, the total number of vacancies required will be about 1000, and even this may not be enough if the demand for British doctors overseas contracts further. The report of the Medical Practices Committee for 1951–52 gives an idea of the present position. During the year the

the W.R. was negative in all cases. Histoplasmin tests were also negative, and so was the Kveim test in the three patients on whom it was performed. All twenty patients were afebrile during the period of observation. In four cases there was enlargement of the peripheral lymph-glands which subsided at the same time as that of the hilar glands. Chaves and Abeles emphasise that the probability of spontaneous regression should be kept in mind when deciding what to do. Irradiation is seldom justified until the diagnosis has been confirmed, and in particularly difficult cases where the lesion is unilateral a thoracotomy may be necessary to identify an operable neoplasm. It seems probable that many of the unexplained cases are the result of persistence of glandular enlargement due to a subclinical infection which has passed unnoticed.

A MIND REGAINED

A SEVERE psychosis may imprison the patient for long periods in an inaccessible world of the mind. People who have suffered this experience have written moving accounts of it, and have been at particular pains to show how apt, sane, and reasonable his behaviour seems to the psychotic. And well it may, for his aberration lies in the false beliefs on which he is obliged to act, not in the responses he is provoked into making to them. Not many writers, however, have described in detail the experience of recovery—the returning interest in the fate of others, and the growing awareness of the hospital—both as a refuge and a place of stress, but also, and above all, as a social community. Mr Paul Hackett, an outstandingly good writer, describes in *The Cardboard Giants*[1] this slow and agonising process of return.

He was a schizophrenic patient in a veterans' hospital in America—a good hospital, as far as he was concerned, though he outlines a darker picture of the blocks for relapsed or chronic cases. He was given able psychiatric care, but there, as here, the numbers of the sick limited the time the psychiatrists could devote to individuals. The attitude of the patients to their doctors is brilliantly sketched: it recalls the response of the multiparous woman to the spinster midwife—a blend of respect for the training and humorous contempt for the ignorance. Among these sick men, however, the contempt was sometimes, and inevitably, bitter.

Mr Hackett came to recognise and integrate two conflicting trends in his own personality, but he does not believe his illness was purely psychogenic. His interest in the physical concomitants of his disorder—particularly the cyanosis of his hands—was roused both by his psychiatrist and by another doctor, a fellow patient, and he willingly collaborated in any shot-in-the-dark measures—such as periods of oxygen-breathing and abstention from coffee and cigarettes—which might be expected to reduce his anoxia. The episode underlines our ignorance of the basic physiology of mental disorders, and the urgent need for research.

NUTRITIONAL RESEARCH IN INDIA

THOUGH he had previously worked on goitre and cretinism, Sir Robert McCarrison's studies of nutritional disease may be said to have begun in early 1918, when he returned to India from active service and was posted to the Pasteur Institute, Coonoor. Built in 1906, for the production of anti-rabies vaccine and the treatment of patients with rabies, this institute is situated in the Blue Mountains amid magnificent scenery, and the climate is mild. McCarrison occupied an empty room in which he started officially to study beriberi, and though his work was twice stopped he twice managed to begin it again. Fortunately in 1926 Lord Linlithgow's Royal Commission on Agriculture visited Coonoor, and with its backing he was able to build up the well-known Nutrition Research Laboratories which he directed until he retired in 1935. His successor there was W. R. Aykroyd, now director of the Nutrition Division of the United Nations Food and Agriculture Organisation, who held the appointment for ten years; and Aykroyd in turn was succeeded by a biochemist, V. N. Patwardhan, under whom are clinical and pathological sections under the clinical scientists, C. Gopalan and V. Ramalingaswami.

Despite the ideal climate of Coonoor, the situation has had two serious disadvantages for the most important centre of nutritional research in India—it is relatively inaccessible and it has no immediate contact with clinical material. Further, although the research laboratories took over the whole of the first floor of the Pasteur Institute and overflowed into a neighbouring jam factory, they have had insufficient space. The governing body of the Indian Council of Medical Research has accordingly decided that they should be transferred to Hyderabad, and on March 31 the health minister for India, Rajkumari Amrit Kaur, laid the foundation stone of the new buildings. In her speech she spoke of the debt India owes McCarrison. "India," she said, "has particular reason to be proud of his achievements, for it was his foresight and, may I say, genius which made it possible to establish these Laboratories as an institution devoted entirely to the study of nutrition." She emphasised the need for pure nutritional research, and for bringing this into intimate contact with those advancing or practising clinical medicine. In Hyderabad the Nutrition Research Laboratories will be closely associated with the hospital and the medical college.

Thus a few days after McCarrison celebrated his 75th birthday his distinguished creation enters on a new and enlarged existence. It has both a fine record and great opportunities.

THE BUDGET

INTRODUCING his second budget last Tuesday, Mr R. A. Butler spoke with more robust confidence than last year, for the adverse balance of payments has been rectified, and his aim of disinflation has been achieved. For the first time since the end of the war no new taxation is proposed, and income-tax is to be reduced by 6*d* in the pound and purchase tax by 25% from present levels. The provision for food subsidies is about £220 million, compared with £250 million last year; this results from decontrolling eggs and cereals. Social services are expected to cost £1264 million—an increase of about £80 million. Referring to the committee which is to review the cost of the National Health Service,[1] Mr Butler said: "I fail to see why it should be called political cowardice for those of us who intend to maintain the health service to have it impartially examined in order that those who pay for it, whether political or non-political, should get value for money spent."

This budget promises a little relief for nearly everyone; but old-age pensioners and others with small incomes may be disturbed by the rising price of their basic foods.

were pneumonias which occurred early, commonly in the prodromal stage or during the first two days of the rash. Otitis media accounted for only 10% of the complications—probably owing to the early use of penicillin for the treatment of pneumonia. An unusual, and quite the most serious, complication was circulatory failure. This appeared most usually in elderly patients and pregnant or puerperal women. It most often took the form of congestive heart-failure, and acute myocarditis was rare. It was thought to be the result of stress on a previously weakened myocardium, mainly in the elderly. Encephalitis was seen in 6 of this series of 1657 cases; and in 4 of these cases the patient died. This gives a rate of 1 case of encephalitis per 275 cases of measles, which is at least three to four times the highest rate previously recorded: and the fatality-rate also was very high. Postinfectious encephalitis, at least the post-vaccinal type, has been said to be rare in the tropics. Is it relatively common in the far North? Of the 26 women in this series who were known to be pregnant, half were delivered at term and half gave birth to premature infants or aborted. No congenital abnormalities were observed in any of the infants born of mothers who had contracted measles during pregnancy.

In this epidemic a very interesting relation was established between measles and tuberculosis. Practically every tuberculous person in the district must have contracted measles, and this very unusual happening seems to have brought an increase both of deaths from tuberculosis and of new cases. In one of the larger villages examination of 352 people immediately before and after the measles epidemic showed 19 new cases of tuberculosis (13 with positive sputum); and among 58 cases of tuberculosis recognised before the epidemic 9 patients died, and at the second examination 13 showed progression. This was clearly more than normal for the district and seems to justify the conclusion that measles reduces resistance to tuberculosis. It was also confirmed, in 51 cases tested, that tuberculin allergy was temporarily suspended during and after measles. The majority did not again become tuberculin-positive until 8–12 days after the rash cleared, and a few cases not until 30–35 days thereafter. Further, no less than 9 cases of postprimary erythema nodosum were observed within a month after the rash. This was thought to be due most probably to a mutation of the bacillus after the temporary suspension of tuberculin allergy.

THE CASE FOR GERIATRICS

TEN years ago the American Geriatrics Society held its first meeting, and this year sees the publication of the first number of its journal.[1] Interest in the welfare of the elderly is increasing rapidly, and the appearance of such a journal is welcome. Medicine in the elderly does not in fact differ noticeably from medicine in the middle-aged, and there are signs of reaction from the former despondent attitude towards the treatment of elderly patients.

It is useful to have a journal devoted entirely to geriatrics, for, as in all pioneer work, there is a tendency to lose sight of the advances, gained or promised, if no attempt is made to create some special interest in the subject. Although medically geriatrics is simply part of general medicine, administratively this work has to be established as a new field for special endeavour: such work as that described by Dr. Andrews and Dr. Wilson on p. 785 shows how much can be done in this way. Probably it is also true to say that much of the advantage to be gained from this approach to the treatment and prevention of disease among the elderly will be lost if in the initial stages these patients are treated and cared for by those whose real interest remains the care of younger persons; for, although it would be absurd to attempt any clear segregation of patients based on age alone, there are some elderly patients who, because of their social background, their general physical condition, or their disease, seem more suitable for the geriatric than for the general physician.

The first number of the *Journal of the American Geriatrics Society* lays emphasis on, among other things, the excellent response of elderly patients to surgery, and shows how, by means of early ambulation, improved methods of anæsthesia, and thorough preoperative investigation and treatment, age can be prevented from being any contra-indication to radical surgery. Such work strengthens the challenge of medicine to our society. Old age can be made active and healthy: what framework can be provided within which life will continue to have a meaning?

ACCIDENTAL INFECTIONS

THE patient's safeguard against accidental infection depends on the vigilance of his medical and nursing attendants, whose "aseptic conscience" may be developed in different degrees according to the nature of their normal work. Agar slopes and tubes of broth are designed to grow bacteria; therefore bacteriologists must either learn a strict aseptic ritual or change their job. The patient in a first-class operating-theatre is safe in the care of a staff well schooled in the practice of asepsis, and his tissues can deal with the few organisms that may be accidentally introduced no matter how carefully an operation is conducted. In the ward, however, the dangers of accidental infection are sometimes less keenly felt, and unexpected disaster may be the consequence. For example, Rabinowitz and Schiffrin[1] report a tragic series of infections caused by *Chromobacterium prodigiosum* (*Serratia marcescens*) in a children's ward of a Jerusalem hospital. The source of infection was apparently a bottle containing 5% glucose in normal saline, which had been used for intravenous treatment. The organism was first isolated in pure culture from two septic wounds. Next it was found as the cause of meningitis in a child, aged 4 months, who died. During the next 2 months the same organism was isolated from nine patients with various lesions involving the skin, meninges, ears, and joints. When the source of infection was traced, and the contaminated bottle discarded, the trouble ceased. The organism was sensitive only to chloramphenicol and aureomycin; and broth cultures killed mice, apparently by the action of a heat-stable endotoxin.

The report by Rabinowitz and Schiffrin confirms other evidence[2] that chromobacteria cannot be disregarded as potential pathogens, and it emphasises that the aseptic standards of the laboratory and operating-theatre must be applied with equal vigour in wards. It is clearly inadvisable, for example, to use the same bottle of glucose saline more than once; in the laboratory any container which has been opened only once, no matter with what care, is no longer accepted as sterile. The importance of applying this doctrine to ward practice is further underlined by the experience of Dr. Michaels and Dr. Ruebner, described on page 772 of this issue, who found that under favourable conditions coliform bacilli may grow quickly enough in some fluids to cause severe effects during intravenous infusion prolonged for more than one day. They suggest that if intravenous therapy is required for several days a new giving set should be used approximately every 24 hours: if the patient has few good veins, the original needle may be left in position. Admittedly, Michaels and Ruebner observed infection in only two cases during 2 years and they found that 5% glucose saline, because it

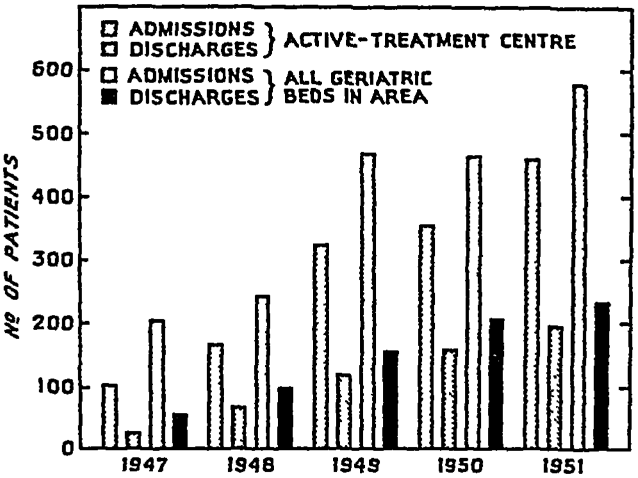

Fig. 1—Admissions and discharges.

the lines of a home, though with facilities for the nursing care of patients confined to bed.

THE ACTIVE TREATMENT CENTRE

A start was made on building up facilities in the active treatment centre in April, 1948. In the course of time the nursing staff was augmented, physiotherapy and occupational therapy departments were initiated, and an almoner was appointed. Radiological and laboratory facilities were made available at the adjacent general hospital, and close contact with the hospital specialist departments was established. As the resources of the geriatric unit improved, the rehabilitation of suitable inpatients was begun. This might mean either the mobilisation of a patient confined to bed for no adequate reason, or a long course of intensive remedial exercises to restore some degree of personal independence to an infirm patient. Considerable difficulty was experienced in returning patients to their homes or relatives when they became fit for discharge, especially when they had been in hospital for a long time. Arrangements had therefore to be made for transfer to welfare hostels of a much higher proportion of patients discharged during this early phase than was found to be necessary later.

TURNOVER IN GERIATRIC BEDS

Gradually, through the discharge of some of the original cases, through the deaths of others, and also through the transfer of suitable patients to the long-stay annexes, an increasing number of beds for new patients became available at the active-treatment centre, and the flow of admissions steadily accelerated. In 1947, before the inception of the geriatric service, some 200 new patients were admitted to these five hospitals, whereas in 1951 575 were admitted—that is, the rate had almost trebled (fig. 1). In recent months there have been indications that this rise in turnover has reached its peak, and that—with existing facilities and the type of patient being treated—no further considerable rise can be expected. It will be seen that not all patients were admitted to the active-treatment centre; about 20% went directly into long-stay beds. These were mainly patients who had been investigated in the wards of general hospitals, and who needed long-stay hospital care. Thus, the patient with inoperable malignant disease or the elderly patient with congestive heart-failure, who was not fit enough for a welfare hostel, are typical examples of this group.

The 575 admissions to 330 beds, in 1951, represents an average annual turnover of 1·7 patients per bed. There were, however, some "inherited" patients who had been in hospital for years and still occupied beds. 1 admitted in 1881 as a young mental defective is still in residence as an elderly dement over seventy years later. As this heritage diminishes in size, the average annual turnover will be in the region of 2 patients per bed.

DEMAND FOR ADMISSION TO GERIATRIC BEDS

Concurrently with this rise in the admission rate, there has been a still larger rise in the number of applications for beds—from 200 in 1947 to 780 in 1951 (fig. 2). This has meant a lengthening waiting-list, especially during recent months, when the rise in admission rate has been slowing down. In 1950, the average waiting time was 15·1 days, and in 1951 it was reduced to 11·6 days, but in the first six months of 1952 it rose to 23·5 days.

TABLE I—SOURCE OF ADMISSION

—	Home	Hostel	Hospital	Living alone
	%	%	%	%
Males	72·8	15·9	11·3	11·3
Females	83·6	6·4	10·0	25·3
Total	79·5	10·0	10·5	20·0

Some method of assessing patients for whom application was made soon became essential, in order that a true picture of the need for beds and of the relative urgency of individual cases might be obtained.

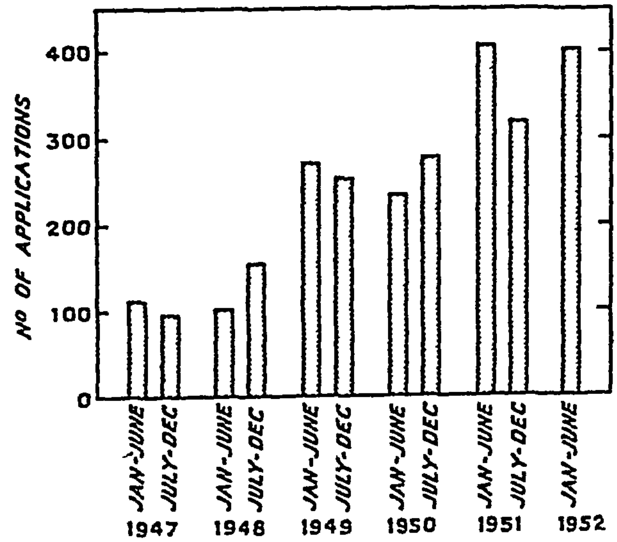

Fig. 2—Applications for admission to geriatric beds.

DOMICILIARY VISITING

Domiciliary visiting of patients awaiting admission has proved valuable. For some patients arrangements other than admission to hospital can be made: those who are suitable can go to a home for old people, run either by the local authority or by a voluntary body, or privately as a rest home. A few patients can be sent to the appropriate special departments for treatment as outpatients. Sometimes a patient can be adequately cared for at home or by relatives if the necessary social props—such as home helps—are provided.

In 1951, 355 patients were visited and 93 were removed from the waiting-list. These represented 12% of the 780 patients referred for admission during that year. For a further 12% a bed was not required when offered either because the patient did not want to enter hospital or because he had died before a bed became available.

REASONS FOR REFERENCE TO HOSPITAL

Analysis of the reasons why patients were referred to the geriatric service revealed a significant difference between this group of patients and those finding their way into general hospitals. Elderly patients in general hospitals were admitted because of [illegible] it, for they refuse to adjust to anything but their original milieu, to which they are always seeking to return. The younger ones form fantasies about their lost parents, and sooner or later develop such signs of instability as anxiety, truancy, aggressiveness, or antisocial behaviour of various kinds. On Jan. 1, 1951, there were 27,263 children in the care of the Seine A.P., of whom 12,591 were under tutelage and 14,772 under protection or confided to care—that is, still having a real or fictitious link with their parents.

It is interesting that in his proposals for relieving this general situation Lelong does not suggest any change in the law which requires this damaging severance of the parental tie. On the contrary, he favours the separation, though at a much earlier age. A child, he says, certainly needs a mother, but it does not particularly matter what mother he has; and to force a mother to take back a child whom she has abandoned, when she has neither the material goods nor the moral qualities to bring him up properly, is not a sound solution. He deprecates those social services which enable a French mother to retain her child while he is an infant, only to discard him when he is older. "Material aid to a mother is illusory when that mother is unfit to fulfil her rôle." This runs counter to current opinion in this country, where we are finding that even a feckless mother may contribute something to her child's development which a deputy, unless highly devoted, finds it hard to supply. Lelong's solution to the problem is an extension of the idea of family placement. He would have the children boarded out with foster-parents or in residential homes where family groups of children of various ages can live under the care of a house-mother. Children would be placed from disposal centres, and would attend clinics for medical supervision and (if necessary) child guidance; social workers would also visit the homes. The older children, he suggests, should live in a "children's village," specially built in the suburbs and consisting of a cluster of "family-group" residential homes, and equipped with its own school and school-teachers. This again runs counter to English experience: we find that children in such homes do best when their house is one of an ordinary row, and they go to the local school and join in the life of the neighbourhood. Separation from parents and segregation from ordinary families are ostracising techniques, designed—it almost seems—to make these deprived children feel acutely, and resent, their difference from ordinary children.

LATAH

THE study of such exotic mental abnormalities as latah and amok has hitherto been left mainly to physicians interested in tropical medicine, to general practitioners working in Eastern countries, and to anthropologists and other non-medical observers. Now a psychiatrist, Dr. P. M. Yap, lecturer in mental diseases at Hong-Kong University, has surveyed latah and related conditions.[1]

Yap regards latah as a psychogenic reaction to a sudden stimulus, mainly to fright, with some hysteriform features, yet distinct from hysteria. The patients, usually middle-aged women, are strongly influenced in their behaviour by their low level of civilisation; latah is a kind of primitive response of the rural illiterate and, perhaps, senile persons with little power of adaptation. The first symptom is a sudden start sometimes followed by a short stupor, echolalia, echopraxia, automatic obedience, uttering of obscenities, and possibly "decomposition of speech." Some patients seem to enjoy demonstrating their symptoms, and others seem to provoke stimulation by inviting to be tickled, which leads to the peculiar behaviour. The patient may be a butt or joke of the village, and in its milder forms the condition is not regarded by the natives as grossly abnormal or morbid. In the more severe cases the patient may struggle against the paroxysms, which fill her with anxiety or anger.

All this is very difficult to place in any one psychiatric category. Yap attempts to group the obvious psychological release of the syndrome with the echo-symptoms and the shameless and coprolalic behaviour occasionally arising in women, apparently caused by organic deterioration. He seeks to relate latah to the culturally simple society in which the patients live; and he compares it with reflex-like fright reactions observed in German soldiers in the first world war. This is by far the most comprehensive account of latah, which, though a relatively harmless peculiarity of elderly women in remote societies, should arouse special interest since it seems to become rare with the intrusion of the Western mode of life.

ENLARGED HILAR GLANDS

WITH the introduction of mass miniature radiography, more cases of asymptomatic enlargement of the hilar glands are being discovered. The people affected are commonly young adults, and students and nurses are often among them. Enlarged hilar glands can usually be identified as smoothly rounded shadows projecting into the lung fields, causing enlargement of the normal hilar roots. Occasionally enlarged glands in the carina cause a backward displacement of the barium-filled œsophagus at this level. But it is sometimes hard to decide whether enlarged hilar shadows are due to dilatation of the pulmonary artery or to glandular enlargement. In these cases a single tomographic cut through the plane of the carina may show the glands situated in the bifurcation of the main bronchi and distinct from the pulmonary-artery shadows.

In generalised diseases of the lymphatic system, such as the leukæmias and Hodgkin's disease, the intrathoracic glands are sooner or later involved; indeed, the first symptoms may be caused by pressure of the glands on the bronchi. In Hodgkin's disease the mediastinal groups are not infrequently the first to be involved. As well as the part they play in the primary complex of tuberculosis, enlarged glands also appear in sarcoidosis and the pneumoconioses, and sometimes in atypical pneumonia and in lobar pneumonia in young children. And of course the segmental glands draining a peripheral carcinoma of the lung become enlarged by lymphatic spread. Involvement of the mediastinal glands may be seen in acute infections, such as glandular fever, german measles, and whooping-cough, and it can also occur in scarlet fever and systemic fungus infection. It is important to remember that the enlargement of the glands may persist for a considerable time after the infection has subsided.

When enlarged hilar glands are found by routine examination of a patient who has no symptoms, a thorough search may in the end show no definite evidence of the cause. Biopsy of suspicious superficial glands, however, may identify the disease; and blood-counts, the Wassermann and Mantoux reactions, and the histoplasmin and Kveim tests may also help. Bronchoscopy is often necessary to exclude carcinoma of the lung.

Chaves and Abeles[1] have now followed up for periods of from 1 to 9½ years twenty patients with asymptomatic enlargement of hilar glands for which no cause could be found. The enlargement subsided in every case, and the time it took to do so varied from 4 to 16 months. Only four of the patients had a positive Mantoux reaction, and in this group the glands took longer to subside than in other patients. The two patients with the greatest glandular enlargement had negative Mantoux reactions. Examination of the blood showed no abnormality, and discharge more rapidly than did the women The average turnover for each active-treatment bed was 6 patients per annum

[1] Yap, P. M. *J. ment. Sci.* 1952, 98, 515.

[1] Chaves, A. D., Abeles, H. *Amer. Rev. Tuberc.* 1953, 67, 45.

Of all patients admitted, 41 1% were discharged, the great majority to their homes or relatives, 31 7% died, and 21 5% required long stay hospital beds (table IV) There was a slightly higher discharge rate and an appreciably higher death-rate among the males than the females, with the result that the percentage of males needing long stay beds was only half the percentage of females Patients who were transferred to long-stay beds, about a fifth of all admissions, included not only those who needed continued nursing care but also the frail ambulant patients who had not become fit enough for a welfare hostel and those mentally infirm patients who although without serious behaviour disorders, remained unsuitable for such a hostel About 42% of these patients were confined to bed

We have not sufficient information as yet to state the average length of stay of a patient in a long stay annexe, but it seems likely that this will prove to be somewhere in the region of two or two and a half years

DISTRIBUTION OF BEDS

The ratio of male to female beds was 1 3, the ratio of the active treatment beds being 1 2 2, and of the long-stay beds 1 3 3 This preponderance of female beds is accounted for by the greater numbers of females requiring admission, the quicker turnover in male beds in the active treatment centre, and the smaller proportion of males eventually requiring long-stay beds The ratio of active treatment to long stay beds was 1 3 2

ESTIMATING REQUIREMENTS

It is possible from these figures to arrive at an estimate of the load which the geriatric hospital service of West Cornwall, or a similar area, with a population of 250,000, might be called upon to carry

In 1951, the number of applications was approximately 800, but about a quarter of these did not require admission, and the real demand was in the region of 600 Probably this figure would have been slightly greater had beds been immediately available on demand Of these patients almost 80% were admitted to the active-treatment centre As has been noted, however, the applications for hospital beds are still increasing It would, therefore, be wise to budget for, say, 1000 requests per annum—a 20% increase on 1951 figures It is not, of course, possible to say how much the load on these beds will increase in the future, but a demand rate of 1000 represents just over 2% *of the aged population*

As each active treatment bed can deal with 6 patients per annum, 100 beds are needed Of these, 31 should be for males, to provide a ratio of male to female beds of about 1 2 2 A small number of these beds (say 6) should be capable of being used for either sex in order to cope with transient fluctuations in demand The number of long stay beds required, being in a ratio of 3 2 1 to the acute beds is 320, of which 74 should be for males The total bed requirement for such a service is 420, of which 105 should be male beds This number of beds provides a ratio of 1 7 beds per 1000 population

WELFARE ACCOMMODATION

It is essential that hospital beds whether in the active treatment centre or in the annexes should not be blocked by patients who do not require hospital facilities

In West Cornwall there are at present 215 'part III accommodation' beds provided by the local authority These are mainly in the former workhouse blocks of the various institutions and are not the most suitable accommodation for old people Two hostels however, have been opened in recent years providing 39 beds In addition, there are 52 beds in three hostels including a home for the blind run by voluntary bodies and a smaller number of beds in privately run rest houses usually with 4 or 5 residents

Of the patients discharged from the geriatric unit during the period under review, about a third went to hostels or old people's homes more could have been discharged had the vacancies been available But the greatest need was for a more sheltered type of hostel for the frail old person, not in need of hospital care yet incapable of climbing flights of stairs—often difficult stone steps in the older institutions These perforce had to remain in a hospital bed

GENERAL HOSPITAL SERVICE

A survey carried out on April 2, 1950, showed the distribution of old people in the hospitals of West Cornwall on that day The hospitals in the area do not serve their own population exclusively there is some overlap with East Cornwall, now in the Plymouth area, from which the West Cornwall Mental Hospital still draws 18% of its admissions The outstanding fact which emerged from the analysis was the high proportion (41 8%) of hospital beds occupied by persons over 60 years of age

About 1 8% of the aged population were in hospital on the day the Census was taken, and of these 35 3% were in hospitals of the geriatric service, a further 17 8% were in general and cottage hospitals The high proportion of old people in the mental hospital (43 0%) is a measure of the increasing load of mental infirmity in old age which the community now carries It is probable that, as elsewhere, admission to mental hospital is often requested as a means of securing a bed, it has been found that, of 2991 patients aged 65 and over in mental hospitals in the South Western Region, 743 (24 8%) do not require mental hospital care but could be housed elsewhere if accommodation were provided

Analysis of the number of patients over 60 admitted in a year (1949) to hospital units of different types showed that 67 6% were admitted to general hospitals with specialist staff This high figure is of course related to the relatively short stay and rapid turnover in these units, the figures of 13 1% and 4 9% for the geriatric and mental hospital services respectively are associated with a much longer period of stay But in any case in 1949 the geriatric service was in its infancy The figure of 351 admissions in that year rose to 575 in 1951 and the percentage of admissions of all aged sick to hospitals of the geriatric service to 21 Of the 575, 70 (12%) were transfers from general and cottage hospitals Nevertheless, a very large amount of work is done for this age group in general and cottage hospitals, and effective cooperation has been achieved between them and the geriatric unit Regular visits to the unit are made by a consulting physician, an orthopædic surgeon, a dermatologist, an ophthalmic surgeon, and a psychiatrist A general surgeon and other consultants are readily available on call Conversely, the advice of the geriatrician is often sought by the general hospitals not only about the disposal, but about the treatment of geriatric patients in their wards Thus the geriatric unit has come to be regarded as an integral part of the area hospital service with the geriatrician a member of its staff committee and of the medical advisory committee of the West Cornwall area

There are no geriatric outpatient clinics in the area nor is it intended to provide these except on a limited scale Outpatient attendance by old people in rural areas often entails a long and exhausting day, particularly if X ray and other investigations are required Attendance for physiotherapy in winter may mean strain and exposure which outweigh any advantage to be gained from the treatment Outpatient clinics in all the main specialties are held in the cottage hospitals and the large general hospitals in the area and attendance at these involves less travelling At Truro and Redruth ov 18% of outpatients attending in one year were over 6 Nevertheless, the actual numbers of outpatient atte it, for they refuse to adjust to anything but their original milieu, to which they are always seeking to return. The younger ones form fantasies about their lost parents, and sooner or later develop such signs of instability as anxiety, truancy, aggressiveness, or antisocial behaviour of various kinds. On Jan. 1, 1951, there were 27,263 children in the care of the Seine A.P., of whom 12,591 were under tutelage and 14,772 under protection or confided to care—that is, still having a real or fictitious link with their parents.

It is interesting that in his proposals for relieving this general situation Lelong does not suggest any change in the law which requires this damaging severance of the parental tie. On the contrary, he favours the separation, though at a much earlier age. A child, he says, certainly needs a mother, but it does not particularly matter what mother he has; and to force a mother to take back a child whom she has abandoned, when she has neither the material goods nor the moral qualities to bring him up properly, is not a sound solution. He deprecates those social services which enable a French mother to retain her child while he is an infant, only to discard him when he is older. "Material aid to a mother is illusory when that mother is unfit to fulfil her rôle." This runs counter to current opinion in this country, where we are finding that even a feckless mother may contribute something to her child's development which a deputy, unless highly devoted, finds it hard to supply. Lelong's solution to the problem is an extension of the idea of family placement. He would have the children boarded out with foster-parents or in residential homes where family groups of children of various ages can live under the care of a house-mother. Children would be placed from disposal centres, and would attend clinics for medical supervision and (if necessary) child guidance; social workers would also visit the homes. The older children, he suggests, should live in a "children's village," specially built in the suburbs and consisting of a cluster of "family-group" residential homes, and equipped with its own school and school-teachers. This again runs counter to English experience: we find that children in such homes do best when their house is one of an ordinary row, and they go to the local school and join in the life of the neighbourhood. Separation from parents and segregation from ordinary families are ostracising techniques, designed—it almost seems—to make these deprived children feel acutely, and resent, their difference from ordinary children.

LATAH

THE study of such exotic mental abnormalities as latah and amok has hitherto been left mainly to physicians interested in tropical medicine, to general practitioners working in Eastern countries, and to anthropologists and other non-medical observers. Now a psychiatrist, Dr. P. M. Yap, lecturer in mental diseases at Hong-Kong University, has surveyed latah and related conditions.[1]

Yap regards latah as a psychogenic reaction to a sudden stimulus, mainly to fright, with some hysteriform features, yet distinct from hysteria. The patients, usually middle-aged women, are strongly influenced in their behaviour by their low level of civilisation: latah is a kind of primitive response of the rural illiterate and, perhaps, senile persons with little power of adaptation. The first symptom is a sudden start sometimes followed by a short stupor, echolalia, echopraxia, automatic obedience, uttering of obscenities, and possibly "decomposition of speech." Some patients seem to enjoy demonstrating their symptoms, and others seem to provoke stimulation by inviting to be tickled, which leads to the peculiar behaviour. The patient may be a butt or joke of the village, and in its milder forms the condition is not regarded by the natives as grossly abnormal or morbid. In the more severe cases the patient may struggle against the paroxysms, which fill her with anxiety or anger.

All this is very difficult to place in any one psychiatric category. Yap attempts to group the obvious psychological release of the syndrome with the echo-symptoms and the shameless and coprolalic behaviour occasionally arising in women, apparently caused by organic deterioration. He seeks to relate latah to the culturally simple society in which the patients live; and he compares it with reflex-like fright reactions observed in German soldiers in the first world war. This is by far the most comprehensive account of latah, which, though a relatively harmless peculiarity of elderly women in remote societies, should arouse special interest since it seems to become rare with the intrusion of the Western mode of life.

ENLARGED HILAR GLANDS

WITH the introduction of mass miniature radiography, more cases of asymptomatic enlargement of the hilar glands are being discovered. The people affected are commonly young adults, and students and nurses are often among them. Enlarged hilar glands can usually be identified as smoothly rounded shadows projecting into the lung fields, causing enlargement of the normal hilar roots. Occasionally enlarged glands in the carina cause a backward displacement of the barium-filled œsophagus at this level. But it is sometimes hard to decide whether enlarged hilar shadows are due to dilatation of the pulmonary artery or to glandular enlargement. In these cases a single tomographic cut through the plane of the carina may show the glands situated in the bifurcation of the main bronchi and distinct from the pulmonary-artery shadows.

In generalised diseases of the lymphatic system, such as the leukæmias and Hodgkin's disease, the intrathoracic glands are sooner or later involved; indeed, the first symptoms may be caused by pressure of the glands on the bronchi. In Hodgkin's disease the mediastinal groups are not infrequently the first to be involved. As well as the part they play in the primary complex of tuberculosis, enlarged glands also appear in sarcoidosis and the pneumoconioses, and sometimes in atypical pneumonia and in lobar pneumonia in young children. And of course the segmental glands draining a peripheral carcinoma of the lung become enlarged by lymphatic spread. Involvement of the mediastinal glands may be seen in acute infections, such as glandular fever, german measles, and whooping-cough, and it can also occur in scarlet fever and systemic fungus infection. Public Health

The Nation's Health in 1951

In his report[1] for 1951 on the state of the public health in England and Wales, Sir John Charles, chief medical officer of the Ministry of Health, says · "We have . arrived at a time when the citizen himself must actively participate in the campaign for better health if further substantial progress is to be made" He points out that most of the improvement in public health over the past century has been achieved without the citizen having had to exert himself or put himself to any great inconvenience, for "a silent army of sanitary technicians has unobtrusively worked this miracle on his behalf" But now the era of sanitary engineering was giving place to that of personal hygiene when "each person must definitely contribute to the common weal"

VITAL STATISTICS

The fall in the birth-rate, which has been declining since 1947, continued the rate for 1951 was 15 5 per 1000 population The report says that the lack of progress in reducing the stillbirth-rate in the last two or three years must be regarded as disappointing and disturbing, particularly when compared with the rapid reduction achieved between 1936 and 1948 The stillbirth-rate rose from 22 7 per 1000 total births in 1950 to 23 0 in 1951 The infant-mortality rate increased very slightly from 29 6 per 1000 live births in 1950 to 29 7 in 1951

The total number of deaths was 549,380—an increase of 39,079 over 1950 Almost all the increase could be attributed directly or indirectly to the severe influenza epidemic during the early weeks of the year The crude death-rate of 12 5 per 1000 population was the highest for several years

COMMON CAUSES OF DEATH

The list of the *most important causes* of death during the year is headed by diseases of the circulatory system (35 9%), followed by cancer (15 7%), diseases of the respiratory system (11 7%), and vascular lesions affecting the central nervous system (12 5%)

Coronary Disease —Deaths attributed to coronary disease continued their 'alarming and perplexing increase, alarming because of the size of the increase perplexing because it had by no means been established that the increases arose solely from a changing fashion in certification though it was undoubtedly a factor of importance" There were 58 309 deaths from coronary disease in 1951, compared with 37,393 in 1947 Hypertension with heart-disease was also appearing more often on death certificates and almost 17,000 deaths were ascribed to this cause in 1951, as compared with 7750 in 1947

Cancer —The number of deaths from cancer and the crude death-rates have increased each year for the past eleven years In 1951 the total was 80,050, which was 810 more than in 1950 The increase in male deaths was again largely due to the deaths from primary neoplasms of the lung, trachea, and bronchus which were responsible for 25% of all male deaths from cancer

Tuberculosis —There was a further considerable decline in deaths from tuberculosis the total number from all forms of the disease was less than 14 000, giving a rate of 315 per million Of this total 12,000 were due to respiratory tuberculosis—2000 less than in 1950 Referring to the welcome increases in nursing staff and in the number of beds available for the treatment of tuberculosis and to the valuable work of mass miniature radiography units the chief medical officer concludes that "it is possible to register a qualified optimism with regard to tuberculosis the end of the battle may be in sight But there were still some unsolved problems calling for further investigation before the final attack was launched

INFECTIOUS DISEASES

Diphtheria, which caused only 33 deaths in 1951, was joining the rare causes of death, and the new low total (661) of notifications also illustrated the success of the immunisation campaign 1951 was the worst *measles* year since notifications were introduced in 1940 there were 616,192 notifications, with 317 deaths The infection was again mild, and "the fall in the case fatality rate continued" In contrast, *scarlet fever* notifications were the lowest on record For the second successive year *whooping-cough* was very prevalent and the total number of cases reported 169,411, was higher than ever before Deaths from whooping cough totalled 457

The number of deaths from *influenza* in the first quarter of the year was greater than in the same period in any of the preceding fourteen years It was estimated that 50,000 people died directly or indirectly as the result of influenza during January and February Influenza was the certified cause of 15,809 deaths—about 12,000 more than in 1950 Since 1918 the proportion of deaths at ages under 55 has gradually decreased in 1951 only 12% of those who died from influenza were under 55, while in 1918 no less than 80% were under that age For the first time in this country absence from work was used as a measure of the progress of an influenza epidemic The outbreak reached its peak in the third week of January when 438,150 people claimed sickness benefit

Dysentery behaved as inexplicably as ever There were 28,561 notifications, the highest number ever recorded and 71 deaths A special subcommittee of the Public Health Laboratory Service has been formed to study the subject Most cases were in outbreaks in day nurseries, residential nurseries, children's hospitals, mental hospitals, and day and residential schools The chief medical officer remarks "Were all meat consumed on the day it was cooked outbreaks in institutions or associated with catering establishments would very soon cease" For the first time since 1942 the number of *food-poisoning* incidents decreased, but "food poisoning, though less prevalent, was still sufficiently widespread to give rise to continued misgiving on our present standards of food hygiene"

There were fewer new cases of *syphilis* and *gonorrhœa* but, the report continues, "we must expect . the appearance of increased neuro and cardio-vascular syphilis consequent upon old and latent infections in fact, the larger numbers of women attending the clinics for the first time for neuro syphilis may represent the beginning of the new host of the afflicted ' Cardio vascular syphilis arising from war-time infection has not yet appeared, but there is little doubt that it will make its presence apparent in due course" Indeed the legacy from the last war was likely to be large, and an extension of routine blood testing would help to discover the thousands who must still be untreated in the late and latent stages of syphilis

NUTRITION

Since the late war, clinical surveys of the nutritional state of the population have shown an almost complete absence of definite evidence of malnutrition or undernutrition In order to provide evidence on which to base future comparisons and with which to detect small deviations, data have been collected from specified groups of children In 1951 observations were confined to boys aged 11 and 17 Boys from grammar schools were on the average taller and heavier than those from modern schools whatever the dietary pattern The factors responsible for this difference seemed to be associated with parental care, higher social group and perhaps parental intelligence Whatever the social class school and family size boys who shared beds were on the average lighter than those who did not and boys whose mothers went out to work were heavier than those whose mothers did not

ACCIDENTS IN THE HOME

Domestic accidents continued to take a heavy toll —between 5000 and 6000 deaths every year The

GERIATRICIAN

WEST CORNWALL GERIATRIC SERVICE

IN July, 1947, the Cornwall County Council invited one of us (C. T. A.) to carry out a survey of aged and chronic sick patients in the seven public-assistance institutions in the county. This paper gives an account of the development of the service which followed.

In the reorganisation which took place after July, 1948, the western part of the county became a "clinical area," with a population of 250,000 and a nearly complete hospital and specialist service. The geographical isolation of this area, bounded as it is on the north, west, and south by the sea, and on the east by Bodmin Moor, has afforded an opportunity to study the problems of providing a geriatric service for a predominantly rural area.

THE SURVEY

The object of the survey was to find out to what extent modern methods of treatment and rehabilitation would be likely to benefit these patients. It was hoped that a considerable proportion of patients might be restored to such a degree of activity as no longer to require nursing care.

The 454 hospital patients were housed in seven joint-user institutions located at Penzance, Helston, Redruth, St. Austell, Falmouth, Launceston, and Liskeard. Later, the units at Launceston and Liskeard were included in the Plymouth clinical area; which left five institutions, housing 303 patients and 190 "house" inmates, as the basis of the service in West Cornwall.

The buildings varied in quality from that at Madron, near Penzance, which had had press publicity ("Pull this workhouse down"), to units of fair quality containing hospital wards of 16–20 beds. In the main they were the same dull drab institutions found in other parts of the country.

There was no modern hospital unit among them, and sanitation was woefully inadequate: on the "house" side, earth-closets were still in use in some places. Heating was by coal fires, and windows were often small and high, which meant patients confined to bed could not see out. In one case, a single bath served 50 male patients. The walls were sometimes unplastered, and the colour scheme was uniformly sombre and depressing. New building, however, was in progress at Falmouth (16 beds) and Liskeard (14 beds).

Traditionally, each institution served its own area and accepted everything that came its way. Thus there were found in the same buildings, and often in the same wards, mental defectives and borderline and certifiable mental patients as well as the chronic sick patient suffering from congestive failure, chronic rheumatism, parkinsonism, or fractured neck of femur, and the occasional acute medical case.

The only medical attention was provided by a local general practitioner calling once or twice a week; he was a busy man and had no time to keep records. Patients were admitted at the request of their general practitioner through the agency of the relieving officer. No clinical details accompanied them, except a document that certified the need for admission. There was no almoner service: patients generally came for life, and the possibility of their return home was never envisaged, either by the relatives or doctor sending them or by the hospital staff receiving them.

Nursing was good in quality but numbers were short. In the seven institutions there were 7 State-registered nurses, including the matrons who were often called upon to deputise for absent staff. The ratio of nursing personnel and ward orderlies of all types to patients was 1 : 5. In the circumstances, it was amazing what good work was done: it was not unusual to find a unit of 50 patients without a bedsore, and moreover there was a bond of affection between staff and patients not always seen in hospitals caring for short-stay patients. But the evils resulting from nursing shortage were real. The bedfast patient was an easier problem to the nurse with her hands full than the frail ambulant patient. So all patients remained in bed; and the evils of the bedfast state were only too apparent in apathy, contractures, wasting, and incontinence. There was no occupational therapy or physiotherapy. The situation in Cornwall was thus no better but rather worse than that in the country as a whole.

A study of 1% sample tables from the 1951 Census shows that the population over 60 amounted in Cornwall to 19·5% of the total population as against only 15·8% for the whole of England and Wales. This higher proportion of the elderly is probably due rather to the large numbers of people who come to live in the county on retirement than to special longevity in the native Cornish. The figures have a practical significance in an area from which the private nursing home has almost entirely disappeared.

The buildings were surveyed with a view to deciding their possible use in an organised service, and the patients were individually examined and classified. The results of the classification were:

	No.
Elderly infirm	42
Acute sick	16
Chronic sick:	
(*a*) Remediable	114
(*b*) Irremediable	162
Psychiatric:	
(*a*) Requiring care in annexe	55
(*b*) Certifiable	8
Mental defectives	39
Blind and deaf	10
Others	8
Total chronic sick	454
Elderly fit patients not examined ("house" inmates)	268

The average age of the chronic sick was 71·2 years.

This investigation showed that we needed to provide both for the investigation, treatment, and rehabilitation of those patients classed as remediable who were already occupying hospital beds, and also for the reception, investigation and treatment of new patients. These were central and closely allied problems. We also needed more effective means of segregating elderly psychiatric patients and mental defectives.

OUTLINE OF THE SERVICE

It would obviously have been neither economical nor desirable to provide the full range of hospital facilities (such as X-ray and physiotherapy departments) in all the institutions. The principle of a central active-treatment unit, linked with a number of peripheral long-stay annexes, was accepted as the framework for the geriatric hospital service of the area.

Barncoose Hospital, close to Redruth General Hospital, and the most central of the five institutions, was chosen for development as the geriatric unit, while the other four institutions were to be long-stay annexes. Remediable patients in the peripheral hospitals were to be brought to the geriatric unit for treatment, being exchanged for patients for whom active treatment in the geriatric centre was no longer required. New admissions were to be taken into the central unit in the first instance, and only those patients who eventually required indefinite hospital care would be transferred to the annexes on completion of treatment. As far as possible, such patients would be sent to the annexes nearest their homes and friends.

The long-stay annexe was conceived as a permanent home, and its development was therefore to be along

In England Now

A Running Commentary by Peripatetic Correspondents

I WAS told that the Central Line was out of action, so I went on the other one as far as Stratford. Crashes never happen on the Underground, and even when I found that typical air of controlled excitement I thought it was due to an unusually complicated breakdown. The unused fire-hose running across the platform was a little surprising, but I thought it was just a precaution. Then coming down the passage as I went towards the exit was a bunch of nurses; they were carrying splints, and bandages in kidney dishes. And the place seemed full of policemen. At the exit there was a mass of press cameras, then I knew that something really had happened. Outside in the narrow street were packed the ambulances, and half a dozen red London Transport vans with notices on the front saying "Urgent," and fire-engines, and police cars. I went on my way, but as more ambulances arrived and joined the queue I wavered and finally went back to see if I could help. Down in the tunnel everybody seemed to be waiting, too—policemen and firemen with walkie-talkie sets and a couple of dozen men and women standing talking. The whole scene was lit brilliantly like a film set, and the quiet voices boomed and echoed. Railwaymen were bringing up cutting tools and cylinders. Somebody said "There's nothing to do. We can't get at them." So we went on waiting. It had happened an hour before, and many of the casualties had been got away but there was so little room to work. I waited in the tunnel until half a dozen doctors (I guessed they were housemen from the local hospital) came out from the train and went back to the surface. There were too many of us, so I went too. It was just like the blitz, with three or four independent services working with complete confidence and apparently nobody giving any orders. There were even the cups of tea. One feels such an amateur when the public services go into action like this.

* * *

Those who teach us, either in the lecture-theatre or by correspondence, often refer to the value of systematic reading, and it is hard to think of a phrase at once so impressive and so awe-inspiring. It conjures up a vision of the human mind as the prepared building site of a vast fabric of knowledge which is slowly but steadily built up over the years till it touches the skies. By systematic reading day by day we add fresh bricks to the growing pile. Everything not only falls firmly into place but stays there, so that in our later years we are, or ought to be, great towers of knowledge to which our juniors can turn whenever they find themselves perplexed. Unhappily it does not always turn out like that. Not all of us have the capacity to read systematically and, even if we have, there are constant interruptions. Memory, moreover, is a fickle jade and not a few of our carefully built-in bricks tumble out and lie scattered untidily among the foundations, which are themselves too often very dicky indeed. Sometimes the gaps remain merely as such; sometimes they become temporarily or even permanently filled up with inferior or shoddy material. Not uncommonly, if we are honest with ourselves, we are forced to admit that the almost completed structure bears less resemblance to a skyscraper than to an untidy ruin; indeed, viewing it objectively, we may legitimately wonder whether it is a structure at all—or ever was.

* * *

"Each to his art" is one of those workaday slogans so well suited to some aspects of the British temperament. The moment the hooter blows, however, it is remarkable to hear how abruptly the note changes to "hand me down my neighbour's tool." Out come the spanners, spades, scissors, palettes, penny-whistles, inkpots, fretsaws, and frying-pans according to taste, and our whole game-but-not-too-gifted nation surges forward on a formidable tide of creation. Not least enviable are members of the Medical Art Society[1] turning from patients to paint. No doubt a psychiatrist (if all they say of art-therapy is true) could detect the bedside form of these self-expressing doctors, distinguishing the physician from the surgeon (and gynæcologist from both), the voluble from the taciturn, the careful from the high-spirited, the mild from the mince-'em-up-alives. I shall not attempt this feat (though tempted), for doc should not eat doc. Let me stick rather to art criticism, which lies so strangely outside the laws of libel.

The medical artists seemed to be happiest among the water-colours, and so was I. A group of four hanging together—*Betteshanger Mine* by C. P. F. Boulden, *Looking South from Gogs Hills* by Henry Wilson, *Ramatuelle* by Edith Whetnall and *Poole Harbour* by Roland Rushton—were all worth looking into for a good long time. I also enjoyed the bold strokes of dark wood against snow in Rushton's *Rue Savoyarde*, and the almost poster gaiety of his *Hayes Common*. Eric Topham's *River Thurne* and Reginald T. Payne's red crayon *The Strand at Rye* both had quality, and I liked the long distances of land and sky in Charles Milner's *Vale of the White Horse*. G. Sparrow had amused himself with reproducing the spirit of eighteenth-century hunting prints in *Point-to-Point*, *the Paddock* and *Cowdray Point-to-Point*; he has the right flavour of caricature and a gay and easy line. But very few of the pictures in the water-colour room deserve to be ignored.

The oils show a lower general level of attainment and more of a scatter round the mean. Since I turn to any picture of a fair-ground as a heliotrope turns to the light, I found myself observing with pleasure the battered, coloured *Steam Engine* of R. A. Beaver, and afterwards with a sad nostalgia, his *The Old Music Hall* painted on a forlorn damp day at Hackney. Quite different from this close and lowering little scene are the wide expanses and pale colours of his *Brooklands*, and another change of light comes with a visit to Sir Philip Manson-Bahr's tropical island, where bold green palms enclose *The church, Rambi, Fiji*. B. E. Barsby-Smith has yet another quality of un-English light in *Dahok, Iraq*. Norman Ashton has done some elegant formal flowers, R. F. Jamieson some *White and Yellow Boats* that somehow lift the spirits, and R. W. M. Strain, in *The Harbour, St. Peter Port*, has been highly extravagant with his paint. H. Elliot Blake's *Palamos Harbour at Dawn*, where little yellow boats are waiting in the misty morning, will please all parties.

* * *

The doctors' Easter has come and gone. Before the holidays I had averaged 30 surgery consultations a day. I closed the surgery on Good Friday and opened again on Saturday. To my mild surprise I was not crowded out with the left-over Friday sufferers who had nursed their pains and licked their sores waiting for the Saturday. On the contrary it was easier than an ordinary Saturday. The sick seemed to have taken a new lease of health.

On Sunday and Monday I was closed, and on the Tuesday steeled myself to receive the accumulated battalions of 48-hours' untreated sick. But, apart from the regulars for their certificates and the medicines as before and an odd one or two sick of a surfeit, business was at a standstill. The chronics of Sunday, Monday, and Tuesday, with their pains here and their aches there and the twittery feelings in the pits of their stomachs, just did not turn up.

Why, one asks oneself, does Easter stay the march of disease, or has it a secret curative influence? Or is most of our daily sickness not really necessary? Will some psychologist kindly explain?

* * *

My fellow peripatetic (April 11, p. 712) will find the formula for Lockyer's pills in the *Dictionary of Practical Receipts* (1848):

Panacea of antimony 10 grains, white sugar candy 1 oz. Make the mass into 100 pills, of which 1, 2, or 3 taken at a time will act as a gentle emetic and aperient.

The Panacea of Antimony is made thus:—

Sulphuret of antimony [illegible] oz., nitre 10 oz., [illegible] 1 oz.; mix in fine powder [illegible] and keep in the fire [illegible] powder and wash it. [illegible] colour.

---

[1] Whose annual exhibition is in progress until April 2[illegible], at Walker's Galleries, 118, New Bond Street, London, W.1. (Weekdays 10 A.M. to 5.30 P.M., Saturdays 10 A.M. to 1 P.M.)

for which they required treatment, and usually for that reason alone; whereas with nearly all the patients referred to geriatric hospitals the physical disability was complicated by a considerable social problem. Only a small number of patients were referred to the geriatric service for purely medical reasons, and these were almost always patients for whom physical rehabilitation was indicated. This social problem is emphasised by the high proportion (20·0%) of patients who lived alone (table I). It is significant that the percentage of women (25·3) in this category is more than double the percentage of men (11·3). When an old person living alone becomes ill, admission to hospital is almost inevitable, for the kindly neighbour is rarely willing, or indeed able, to look after him for long.

Disorders of behaviour placing an intolerable strain on the domestic structure also lead to admission: 19·0% were confused and irrational on admission, and 23·0% incontinent of urine or fæces. The social difficulties of these patients influenced both the effect of treatment and their disposal on discharge: it was often found that patients did not make the expected progress until the problem of their future had been solved.

TABLE II—AGE-DISTRIBUTION

—	Under 60	60–69	70–79	80–89	90 +	Total
	%	%	%	%	%	%
Males	5·3	18·0	48·9	26·3	1·5	100
Females ..	7·3	19·4	35·3	32·8	5·2	100
Both sexes ..	6·6	18·9	40·2	30·4	3·9	100

Between August, 1950, and June, 1951, 365 patients were admitted to the active-treatment centre, 133 (36·4%) being males and 232 (63·6%) females. The ratio of females to males was thus 1·7 : 1. Their age-distribution is shown in table II; most of them were between the ages of 70 and 90, with an average age of 76. The average age of the females was somewhat higher than that of the males—77 as against 74—and there were more females than males aged 80 or over.

CLINICAL GROUPING

Certain well-defined clinical entities appear to gravitate to geriatric beds, such as cases of stroke, arthritis, and other conditions requiring physical re-education and reablement. More than one disorder was an almost invariable finding. In the main, however, the patients were infirm old people with ill-defined senile disabilities complicated by unfavourable social circumstances, who required investigation and treatment of their physical complaints and a solution of their social problems. The following clinical conditions were found among them:

	No.	%
Hypertension	102	28·0
Congestive heart-failure	67	18·4
Coronary occlusion	16	4·4
Cerebrovascular accident	75	20·5
Senile dementia	47	13·0
Chronic bronchitis	7	1·9
Acute pulmonary inflammations	46	12·6
Neoplasm	27	7·4
Fractures	24	6·6
Advanced arthritis	18	4·9
Paget's disease	4	1·1
Pernicious anæmia	7	1·9
Other severe anæmias	13	3·6
Diabetes	18	4·9
Thyrotoxicosis	3	0·8
Myxœdema	2	0·5
Cholecystitis	6	1·6
Peptic ulceration	5	1·4
Ulcerative colitis	3	0·8

As might be expected, cardiovascular disorders formed a high proportion.

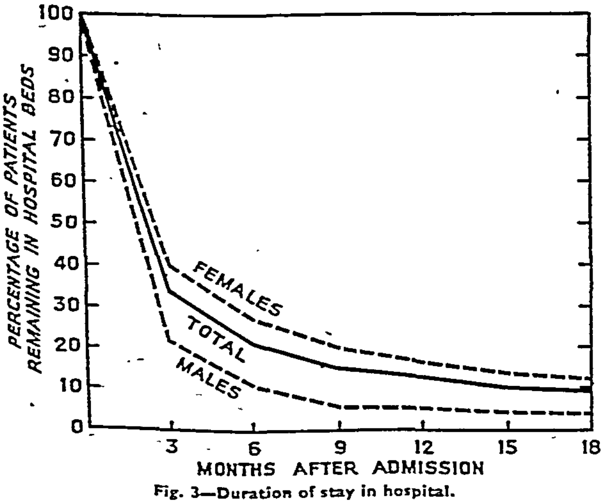

Fig. 3—Duration of stay in hospital.

TABLE III—DURATION OF STAY (WEEKS) IN ACTIVE-TREATMENT BEDS

—	Discharged	Died	All patients
Males	10·5	3·3	7·5
Females	13·5	3·6	9·9
Both sexes	12·2	3·5	9·0

Some 28·0% of the patients suffered from hypertension. A systolic blood-pressure of 190 mm. Hg or over, or a diastolic pressure of 120 mm. Hg or over, or both, were the criteria accepted for such a classification. The high proportion of patients (almost a fifth) who suffered from congestive heart-failure indicates the extent to which this clinical group—many of whom would formerly have been admitted to general hospitals—now tend to come into geriatric beds. The fact that 20% of the patients suffered from a cerebrovascular accident of more than minor degree and that over 10% had advanced arthritic conditions and fractures (usually fractures of the neck of femur) indicates that the rehabilitation load was considerable.

TABLE IV—FATE OF PATIENTS ON LEAVING ACTIVE-TREATMENT BEDS

—	Discharged	Died	Transferred to	
			Other hospitals	Long-stay beds
Males	42·9%	37·6%	6·0%	13·5%
Females	39·7%	28·4%	5·6%	26·3%
Both sexes ..	41·1%	31·7%	5·7%	21·5%

Acute pulmonary inflammations were present in a significant proportion. A neoplastic condition was detected in only 7%, the gastro-intestinal tract being the site of the neoplasm in almost half these cases. Anæmia of severe degree was present in about 5%; diabetes was the commonest endocrine disorder; and peptic ulceration was relatively uncommon.

Only a third of the patients occupied a bed for more than 3 months, and at the end of eighteen months only 12% of the patients still remained in hospital (fig. 3). There was a significant difference between the sexes, the percentage of males remaining at the end of each quarterly period being much less than that of the females. This greater rapidity of turnover in male beds is borne out by an analysis of the duration of stay of patients in active-treatment beds (table III). The average stay for all patients was just over two months. The men averaged only 7·5 weeks, however, as compared with 9·9 weeks for the women. This was due not only to the fact that the men who died did so after a slightly shorter stay in hospital than the women but also to the fact that those men who were eventually discharged became fit for

JUNIOR HOSPITAL STAFF

SIR,—If anything, Dr Gee, in his letter of April 4, understates the position If we are right in our interpretation of the signs, something like a breakdown in the junior staffing of regional-board hospitals appears to be imminent The result will be a catastrophic fall in the standards built up since 1948

In view of the muddle and inhumanity which have characterised the Ministry's handling of the senior-registrar problem, it is not surprising that it is already proving difficult to find suitable applicants for registrar appointments in peripheral hospitals

It appears to us that the main reason for this lamentable situation is that the Minister's main advisers have been from the teaching hospitals

A R KELSALL
Watford C W C KARRAN

TRICHOMONAS VAGINITIS

SIR,—A disease is important, apart from any clinical or pathological interest, if it is common, difficult to treat successfully, and a cause of much distress By these criteria trichomonas vaginitis is indeed important and needs every effort to prevent and cure it In addition it is a serious social disease by reason of its malign effect on married life Not only does the local pain and tenderness often prevent coitus until finally it is cured, but it *may even break up a marriage* Recently I have seen a young married couple, with one baby, tortured by the frustration of compulsory abstinence which has finally separated them, and most gynæcologists have seen similar domestic tragedies

You are right when you say (April 4) that it has been a neglected disease, though not by the immense amount of investigation of the parasite and attempts at treatment Trussel's monograph, giving some 1200 references, is evidence of the amount of attention devoted to this baffling infestation The neglect is in the day-to-day clinical management in outpatient clinics Vaginitis is regarded more as a nuisance than a serious affliction, and this often leads to perfunctory treatment

All the severe cases in which the vulva and vagina are too tender for any outpatient treatment, and all relapsing cases, should be admitted to hospital for thorough disinfestation under anæsthesia This must be followed by repeated visits to the outpatient department for further treatment through a speculum It is entirely useless to expect a cure by instructing the patient to insert a pessary each day She cannot place a pessary—many more than one are needed—in the fornices around the cervix where the parasite can maintain itself even though the lower vagina is bathed by the melted pessary

Mr McCullagh (April 4) is probably right when he incriminates the oval lavatory seat, though I believe he exaggerates its importance If it is the chief factor why do we so seldom see the disease in virgins, in children, and after the menopause? Occasionally cases arise in these groups, but relatively the number is very small compared with the incidence in married women

The interesting experiment described by Dr Lanceley and Dr McEntegart (April 4) *shows not only that the* male urethra can harbour *Trichomonas vaginalis* but also that two of their cases were infested *for some weeks*

My own view, after having considered and treated some hundreds of patients, is that the disease is chiefly communicated by coitus with an infested man

London W 1 ALICK BOURNE

THE GAP SEAT

SIR,—Mr McCullagh (April 4) exhorts medical practitioners to demand the introduction of the gap type of non-infecting lavatory seat in public lavatories

The reform he advocates is inadequate What is required is the abolition of the lavatory seat and the basin thereunder and their replacement by a squatting platform The obvious advantages are (*a*) the feet are the only part to have contact with the lavatory, (*b*) the lavatory can be cleansed with a water jet from a hose pipe, (*c*) the squatting position maintains better tone of the abdominal and perineal muscles, (*d*) "bearing down" does not induce inguinal hernia, and (*e*) evacuation is more effective For perfection water replaces toilet paper, and facilities for hand-washing will in any case be available

As many of us know, this is a matter in which the East can teach the West

J. H HUDSON
Dartford, Kent Medical Officer of Health

OSTEOPATHY

SIR—I, in turn, would like to correct any false impression created by Dr Turner's letter (March 28).

Dr Turner has obviously never watched Dr Cyriax dealing with a case of intervertebral-disc displacement His examination and diagnosis is made with great care and skill, and his treatment is carefully worked out according to the history and physical signs Manipulative treatment is only given in about half his cases But when given, it is not a method of "uncontrolled torsional forces" After each careful manœuvre the patient is re-examined and his condition assessed If there is an improvement the manœuvre is repeated, if not the next manœuvre is performed and the patient again re-examined

Dr Cyriax's results compare very favourably with any others I have practised his methods for nearly five years, and a failure to cure is exceptional I should like Dr Turner to hear the complimentary remarks by patients (*I am one of them*) treated by these methods.

Dr Turner's remark about "the process of reductio ad absurdum" is, in itself, absurd He implies that the osteopathic methods will reduce living tissue, whereas Dr Cyriax's can only reduce "dry friable matter" Again the answer is in the results

Hoddesdon, Herts R BARBOR

SIR,—Sir Charles Symonds in his very able article on cervical spondylosis (March 7) was obviously stressing the great need for adequate diagnosis This would seem to be a prerequisite for therapy of any kind, and if one teaches therapy to an auxiliary therapist for even x number of years, it will not increase his ability unless he is also taught pathology and the correct interpretation of the signs and symptoms of disease Physiotherapists are not taught thus

The osteopath is taught in this way He has to study the basic sciences and receives long tuition in the craft of manipulation—which is why he does apply manipulation with discretion

The argument will, of course, lead many once again to confuse osteopathy and manipulation These rather naive blessings upon, and acknowledgments of, the osteopath's skill ignore all question of the theory behind the physiological consequences of manipulation, assuming that the osteopath manipulates, as the orthopædist does, just plainly to mobilise, as though rigidity were in itself a bad thing and mobility the reverse Lack of mobility, spondylosis or any other outcome of morbidity is not the disease but its result, and manipulation applied to any such effects will do nothing to cure the disease although perhaps relieving it

The osteopath will apply manipulation on much more of a strategic basis, possibly leaving an area of spondylosis entirely alone, while convinced that his treatment to the spine in other areas can provoke physiological consequences beyond mere mobility and in the direction of reducing the process of disease from within

General Council and Register R F MILLER
of Osteopaths Ltd Registrar
[illegible] Buckingham Street London W C

dances are low when it is remembered that the aged in Cornwall constitute 19·5% of the total population, and when their high morbidity-rate is considered. They suggest that outpatient clinics are of limited value for this age-group, and seem to argue against the establishment of special outpatient geriatric clinics, at any rate in rural areas. In contrast, of 2609 recent domiciliary consultations in this region, 37·4% were made to patients over 60. The services of the geriatrician and his staff should be freely available for home visiting, not only in an advisory capacity, but for such simple investigations and treatment as are practicable in the home. The almoner can be particularly helpful in making arrangements for the care and disposal of the patient elsewhere than in hospital.

DOMICILIARY SERVICES

If Sheldon's figures for Wolverhampton [1] apply to the country as a whole, the great bulk of the load of infirmity in old age is being carried by the home. No comparable survey has been carried out in Cornwall but it may be useful to note, in passing, the various ageneies which help to give domiciliary service in this as in most other rural areas.

1. *The Family.*—Family ties are strong among the rural population and there is less tendency than in the cities for every member of the family to go out to work. The load is most often carried by a daughter when the mother is ill and by the wife when it is the husband.

2. *The Good Neighbour and Relatives.*—In such a rural area as this, the relatives often live in the same, or a neighbouring, village. Probably at least 80% of cases of infirmity in the home are cared for without recourse to professional nursing help.

3. *The district nurse*, 34% of whose patients in this area, according to a recent study, are aged 60 and over, pays 48·7% of her visits to members of this age-group.

4. *The health visitor* can help by providing assistance for patients awaiting admission, by preparing the way for discharge of patients in hospital, and by subsequently following them up. The nursing officers in charge of the five local health authority areas in West Cornwall pay regular visits to the active treatment centre, where they see patients from their own areas, and discuss any necessary arrangements with the hospital almoner.

5. *The home-help service*, provided by the local authority, is still in its infancy in West Cornwall. However, a good start has been made in organising part-time and "good neighbour" help in the villages. A woman who lives in the same village can be much more knowledgeable on the social problems of her aged patient and much more readily available for the large number of chores for which her services are required.

6. *The general practitioner* carries, and must continue to carry, the main responsibility for medical care in the home. He would benefit considerably by closer liaison with the geriatric service.

LIAISON

The need for liaison arises not only in the domiciliary service, though it is most obvious here because of the number of bodies concerned. Within the hospital service itself there is need for close coöperation, in view of the large amount of work undertaken for old people by nearly all specialties. Between the hospital authority and local authority, the need extends from the level of planning to the care and disposal of the individual patient. We have been fortunate in West Cornwall in having virtually only one hospital management committee and one local authority. We have also been fortunate in the favourable attitude of people and press, and in the ready help given by the Council of Social Service for Cornwall. Nevertheless, the lack of a body with statutory powers to coördinate the activities of all the various committees is sometimes apparent; and a joint planning committee, representing hospitals, general practitioners, local and welfare authorities, and voluntary bodies, is now projected.

SUMMARY

An account is given of the development of a geriatric service in a well-defined geographical, and predominantly rural, area with a population of 250,000.

The service was based on the existing public-assistance institutions, and now consists of a central active-treatment unit linked with peripheral long-stay annexes.

This arrangement made it possible to admit, in 1951, almost three times as many patients as were admitted to the same number of beds in 1948.

We estimate that, in an area like ours, about 1·7 geriatric beds are needed per 1000 of population. In West Cornwall this figure represents 9 beds per 1000 of the population over the age of 60; but the age-structure of the population varies from area to area.

The ratio of long-stay to active-treatment beds should be in the region of 3·2 : 1, and the ratio of male to female beds 1 : 3.

The need for homes and hostels for discharged patients is emphasised.

The part played by the general and special hospitals is illustrated by the fact that, on a given day, 1·8% of the aged population were in hospital, 0·7% in hospitals of the geriatric service, and 1·1% in general and special hospitals. Beds occupied by patients over 60 accounted for 41·8% of the total.

The limitation of the general outpatient services is discussed and the importance of the domiciliary services emphasised. In this area, with 19·5% of old people, the proportion of outpatient attendances in the over-60 group was 18·5%; and 37·4% of those needing domiciliary consultations were in this group.

SCOTTISH REGIONAL HOSPITAL BOARDS

THE Secretary of State for Scotland has made the following appointments to the five Scottish boards. Out of 27 appointments, 18 are reappointments of retiring members. Those now appointed will hold office until March 31, 1956. The names of doctors are shown in bold type:

NORTHERN REGION

Reappointed: Miss M. B. Clyne, S.R.N.; Rev. Father Neil MacKellaig; G. Ralph; J. South.

New member: Rev. A. Gemmell, F.PH.S.

NORTH-EASTERN REGION

Reappointed: D. Cochran, LL.B.; Provost H. J. Milne, M.C.; R. Ollason; Mrs. J. Wolrige-Gordon.

New members: R. Esslemont; Miss Bell Jobson (till March 31, 1955).

EASTERN REGION

Reappointed: W. I. Brown, J.P.; Prof. **W. L. Burgess**, F.R.C.P.E.; Miss M. C. Cameron, S.R.N.; Councillor J. R. Christie.

New member: **J. C. Anderson**, M.B.

SOUTH-EASTERN REGION

Reappointed: **W. Boyd**, M.B.; Councillor R. Burnside, J.P.; Bailie D. R. Matheson, LL.B.

New member: **G. J. Summers**, M.B; two vacancies.

WESTERN REGION

Reappointed: **T. Anderson**, F.R.F.P.S.; **P. K. McCowan**, F.R.C.P., J.P.; J. Stewart, J.P.

New members: **R. S. Barclay**, F.R.C.S.E.; D. Burns; W. H. Dunlop, C.A.; P. R. Jacobs; A. M. Robertson, J.P.; **J. Bruce Dewar**, F.R.C.O.G., J.P. (till March 31, 1954).

The Secretary of State has made a slight reduction in the size of the boards; the number of members (excluding the chairman) is now as follows: Northern region 16, Northern-Eastern region 18, Eastern region 18, South-Eastern region 23, Western region 29.

words, we earned about 6 units a day! But a good deal of the unofficial work we did laid the foundations of modern routine. Lastly, we refused to "accept" any published *technique*, "standard" or "pirate," until we had given it a thorough trial.

I venture to suggest that were it possible for analysts in hospital laboratories to adopt these principles, results in trials such as that reported by Dr Wootton and Professor King would be closer.

Chichester, Sussex G. A. HARRISON

DISORDERS OF MOTILITY OF THE SMALL BOWEL

SIR,—Mr MacPhee's article (April 4) was of especial interest to us as a similar case to that described by him was seen at this hospital in November, 1952. In this case treatment relieved the patient's symptoms.

The patient, a man aged 62, had a partial gastrectomy in 1942 for a duodenal ulcer, and after this operation he always had loose pale motions. In January, 1952, he began to have persistent central abdominal pain unrelieved by food or alkalis. There was nausea but no vomiting, some regurgitation and eructation of a foul-tasting gas. Diarrhœa—consisting of 4–5 soft putty-coloured stools daily—was constantly present. The patient had lost about 2 stone in weight from the onset of the symptoms, had gradually become dyspnœic on exertion, and had had swelling of the ankles for 3 weeks. He further complained of a sore tongue and of cracks at the angles of his mouth.

A gastrocolic fistula was suspected, giving rise to anæmia, hypoproteinæmia, and riboflavine deficiency.

A barium meal and barium enema excluded the presence of a gastrocolic or jejunocolic fistula. Passage through the small intestine was rapid, the barium reaching the transverse colon in 2 hours; segmentation of the barium in the small gut was seen. The hæmoglobin was 50%, red blood cells 2,000,000 per c.mm., colour index 1·2. Sternal marrow showed active erythrogenesis in excess of normal; megaloblasts predominated among the red-cell precursors. Stool examination revealed no pathogenic organisms, but undigested meat fibres were present. Charcoal and gentian violet given orally were present in the stools in 3–4 hours.

Treatment was carried out as follows: the hypoproteinæmia was corrected by a high-protein diet, the anæmia by a blood-transfusion, vitamin B_{12} injections and iron by mouth, which resulted in a good reticulocyte response; the diarrhœa was treated with codeine phosphate and folic acid, and the ariboflavinosis with injections of vitamin-B complex ('Becosym').

During the next 3 weeks the diarrhœa lessened but was not completely controlled; the hæmoglobin rose to 70%; the œdema disappeared and the cheilosis improved slowly; but the patient remained depressed and still complained of abdominal discomfort and regurgitation.

It was thought that the pancreatic enzymes were unable to act, owing to the contents of the stomach passing rapidly into the small bowel; and pancreatin and sodium bicarbonate were added to the treatment. The patient's condition improved immediately. The pain ceased and there was no further regurgitation. The stools became formed, the hæmoglobin rose further, and the patient gained weight. On leaving hospital 2 months after admission his general health was satisfactory.

It therefore appears that in some people an inherent weakness of the small bowel, when thrown into prominence by subtotal gastrectomy and then giving rise to a clinical picture akin to that of gastrocolic fistula, can be corrected by suitable medical treatment.

Wanstead Hospital,
London, E.11.

ERIC FRANKEL
J. LEWIS MOORE

SIR,—Mr MacPhee has drawn attention to the "much neglected field of small bowel function," and articles such as his may well herald an increased interest in the small intestine. May I suggest that in future studies details of the barium preparation should always be given. My colleagues, Dr J. M. French[1] and Prof. A. C. Frazer, have shown that the so-called deficiency pattern is really a property of the barium rather than the gut, for barium sulphate flocculates when mixed with mucus, and this accounts for the segmentation seen on radiography—an outline that bears little or no relation to the contour of the bowel wall itself. When a non-flocculating barium suspension is used in such cases, the bowel is usually dilated, so that the appearance of spasm is probably an artefact.

In our studies on the sprue syndrome, we use routine barium sulphate initially, as the flocculation pattern is a useful diagnostic guide to the presence of a fat-absorption defect. A non-flocculating barium is, however, essential to outline the intestinal wall and to obtain a mucosal pattern; otherwise such conditions as jejunitis may easily be missed.

Birmingham. C. F. HAWKINS

PITUITARY-THYROID RELATIONS

SIR,—In a recent annotation (Feb. 28) you consider the thyroid-pituitary relationship in Graves's disease and mention a paper from this laboratory.[1] The results of present work, though incomplete, may thus be of interest.

Briefly the argument advanced by us against the pituitary having any part in the production of Graves's disease included the demonstration that the actively hyperthyroid gland responded to small doses of exogenous thyrotropin and could not be suppressed by the administration of large doses of desiccated thyroid. You point out the weaknesses inherent in the use of whole thyroid and cite the experiments of Morgans et al.[2] with sodium *l*-thyroxine, which gave results comparable to those with the whole gland. These two experiments, however, leave unsettled the possibility that insufficient hormone was administered to suppress the pituitary.

EFFECT OF TRIIODOTHYRONINE FOR 7 DAYS IN GRAVES'S DISEASE AND IN EUTHYROID SUBJECTS

Patient	Daily dose	Serum protein-bound iodine (µg. per 100 ml.)		Radio-iodine uptake (%)	
		Initial	After treatment	Initial	After treatment
S. I.	1 mg.	11 2	12 3	71	74
N. S.	2 mg.	11 0	11 2	77	[illegible]
R. F.	"	17 2	17 8	73	67
S. I.	"	9 4	11 6	64	[illegible]
P. M.	"	11 2		49	[illegible]
S. I.		13 0	11 7	96	[illegible]
V. V.	"	10 5		67	62
		Control			
P. M.	70 µg.	3 9	4 3	29	[illegible]
I. H.	100 µg.	4 8	[illegible]	33	[illegible]
H. H.	70 µg.	3 8	2 4	21	[illegible]
N. M.		4 1	2 1	20	[illegible]
N. H.		4 6	4 6	33	[illegible]
I. S.	"	4 6	4 6	30	4
		Non-toxic diffuse goitre			
M. M.	2 mg.	4 0	[illegible]	[illegible]	15

This possibility has been under investigation in this laboratory. Triiodothyronine has been given in large dosage to patients with active hyperthyroidism. This agent, isolated by Gross and Pitt-Rivers,[3] is more potent and acts more rapidly than thyroxine. The daily dosage in our experiments—2 mg. daily—is roughly equivalent to 8 mg. sodium *l*-thyroxine or 2·4 g. desiccated thyroid daily. Alarming exacerbations of disease resulted during the week of administration, and in the one patient in whom the basal metabolic rate was repeatedly estimated this rose from +27% to +67%.

The pituitary and hence thyroid was not significantly depressed by these large doses of triiodothyronine (see accompanying table). This tends to rule out the same age-groups were particularly affected; about 20% of the fatalities occurred in children under five years of age and about 60% in people over sixty-five. More children under fifteen died from accidental causes in their homes than were killed on the roads: and between the ages of one and five a fatal home accident was still one of the commonest causes of death.

Smallpox

Another 2 cases of smallpox have been reported from Lancashire and the West Riding during the week ending at noon on April 14. The total number of cases is now 23; and 1 of the new patients, a boy, aged 8, living in Leeds, has died, bringing the total of deaths to 5. The boy, who was unvaccinated, fell ill on April 6. A rash which appeared on April 8 was diagnosed as measles. He was admitted to hospital on April 11 and vaccinated, but he died on April 14. A confident clinical diagnosis of hæmorrhagic smallpox awaits laboratory confirmation. The source of infection has not yet been traced. This is the first case in Leeds during the outbreak. The second patient, a 17-year-old girl in Oldham, had already been in quarantine as a contact and had been vaccinated on March 20. She became ill on March 29, and this illness has now been confirmed as modified smallpox. In Todmorden, where workers at a cotton mill were the first to be infected, Dr. J. Lyons, medical officer of health, said[1] on April 13 that all contacts were out of quarantine in the area and the town might be regarded as free from the disease. Quarantine restrictions were lifted at Halifax General Hospital on April 13 after the 2 remaining suspects had been found to be free from infection.

Diphtheria

Last year there were only 31 deaths from diphtheria in England and Wales, the lowest figure ever recorded. This compares with 2480 deaths in 1940 when the national immunisation campaign opened. But in telling local health authorities of the publicity material available for this year's campaign, the Minister of Health, Mr. Iain MacLeod, stresses that the complete elimination of the disease depends upon the maintenance of an adequate level of immunisation. Sustained publicity by local authorities is essential if parents are to be helped to realise that diphtheria is still a deadly threat. The target for this year is the immunisation of 500,000 children under the age of one.

Metropolitan Water Board Jubilee

After the disastrous cholera epidemic of 1854, routine chemical examination of London's water-supply was introduced in 1858, and in 1871 the position of Government water examiner was established by statute. From about 1882 onwards the isolation and examination of bacteria provided a much more delicate test for assessing pollution or establishing purity; and in 1885 routine bacteriological examinations of the Metropolitan water-supply were started. Then, in April, 1903, fifty years ago, the Metropolitan Water Board held its first meeting in the council chamber of the Privy Council in Downing Street.

Today the board supplies approximately 320,000,000 gallons of water to a population, in round figures, of 6,500,000—one-seventh of the total population of Great Britain. The rivers Thames and Lee provide most of this water, but storage reservoirs are necessary to meet users' needs to the full in a period of drought. Much work is being done to raise output, increase efficiency, and secure economy, and to ensure that methods of waste detection and suppression and of water examination and treatment are of the highest standard. A large filtration and pumping station, with a capacity of 90,000,000 gallons daily, is being built in the Thames valley at a cost of over £4,000,000; and a 75-inch main to carry raw water from the Thames to the Lee valley is being planned. A Government white-paper of 1944 stated: "Not so many years ago it was thought in responsible quarters that London would have to abandon the use of the Thames and the Lee, but today 90% of London's water—bacteriologically one of the purest in the world—comes from these two rivers."

Although the increase in urbanisation and pumping has made it necessary to chlorinate all water from wells, in only a few cases is filtration required. But the river-supplied water, polluted by domestic sewage, trade waste, and plant life, needs elaborate methods of purification. After storage in the large reservoirs, all river supplies are filtered. The ordinary slow sand filtration, first used by the Chelsea Waterworks Co. in 1829, was replaced in 1923 by rapid primary filtration, which removes the larger suspended matter before the water is passed to the slow secondary filters. The board now uses nearly 200 slow sand filter beds, 100 primary filters, and 12 mechanical filters. The ultimate guarantee of purity is conferred by chlorination. Chlorination was first used in the early years of this century; and in 1921 the board began chlorinating filtered river water before it was passed into supply. After 1936 all water was treated by the ammonia-chlorine process, and since 1948 the latter process has been replaced by superchlorination, which has improved the physical quality of the water and its bacterial purity more than any other measure since the introduction of sand filtration.

The board's water examination department at New River Head is divided into three sections: the biological section concentrates on the conditions of the reservoirs and rivers and their treatment; the bacteriological section is concerned with the improvement in the bacterial quality of the water as it passes through the various stages of purification and with the safety of the final water for domestic consumption; and the chemical section deals with chemical treatment and with the examination of the chemical and physical quality of the water, including clarity, colour, and taste. During 1952 the total number of samples collected for all purposes exceeded 93,000.

Improved Physique of Glasgow Children

In his report on the medical inspection and treatment of school-children in Glasgow during the year ended July 31, 1952, Dr. James Ewan, principal medical officer of the education health service of Glasgow, refers to the gratifying results of routine inspection. Fewer children were found to be abnormal; 42·8% of all the pupils examined were recorded as having no defect of any kind—the highest proportion since the establishment of routine medical inspection of school-children in Glasgow in 1909. Moreover, of those children who were found to be abnormal, fewer than ever before had the less remediable type of condition. Average measurements also showed improvement, and only the weights of the 5-year-olds (particularly the girls) failed to conform to pattern. For example, in 1952 13-year-old boys were on the average 0·62 in. taller and 1·65 lb. heavier than boys of the same age in 1945; and for girls the corresponding increases were 0·32 in. and 1·75 lb. During these 7 years, the average measurements for 9-year-old boys rose by 0·56 in. and 1·02 lb., and for girls of the same age by 0·42 in. and 1·08 lb. Defective vision was also less common, and the proportion (14%) of children whose sight was below normal was less than in any previous year except 1949.

or conversely above 32°C the blood-flow may show a continued increase without a rise in surface-temperature

I also agree with Dr McPherson that the temperature changes recorded on exposure to room-temperature in the patients with diabetic neuropathy were so small as to be insignificant But then, of course, this was interpreted as indicating no change in the state of peripheral vasoconstriction or vasodilatation

THE PROBLEM OF PEPTIC ULCERATION

Sir,—In his letter of April 4, Mr Downie invites opinions on the treatment of high gastric ulcers In 1933 I devised (as I thought) the operation of gastrectomy below the ulcer,[1] which I now know should, by priority, be attributed to Madlener It is not often necessary but produces excellent results, and I have found no reason to regret it Of course carcinomatous ulceration must be excluded today with greater certainty than was necessary twenty years ago, because of the increased possibility of its resection It is also necessary nowadays to think about the possibility of diaphragmatic herniation and retraction of the cardia, both of which may be associated with high gastric ulcer This last combination, however, is also probably best treated by gastrectomy below the ulcer

SCHOOL ORTHOPÆDIC CLINICS

Sir,—I found the special article on school orthopædic clinics by Mr Hulbert (March 14) of great interest

As a result of a certain amount of experience obtained in work in school clinics, I came to the conclusion that minor degrees of symmetrical knock-knees in children were normal and, as Mr Hulbert points out, subject to spontaneous cure

I claim no originality for the following explanation, although I have not seen it mentioned before If it is assumed that the external angle between the femur and the tibia when fully extended, remains constant during growth, it stands to reason that as the neck of the femur grows and as the distance from the acetabulum to the midline increases, so the lower end of the tibia tends to approach the midline Counteracting this tendency is the natural growth in length of the shaft of the femur, but if this increase in length is proportionately less than the increase in distance from the midline to the great trochanter then the apparent knock knees disappear

VITAMIN E AND INTERMITTENT CLAUDICATION

Sir,—Dr Hamilton and his colleagues (April 11) have misread my letter. I did not criticise them for trying to prove a null hypothesis but for drawing the invalid conclusion "that vitamin E is of no value in the treatment of intermittent claudication" I cannot accept "condensation" as an excuse for an invalid conclusion brevity should be no hindrance to precision

If as they say, they were really trying to prove the null hypothesis (that vitamin E has no more effect on intermittent claudication than an inert substance), then the "double blind" principle is useless This principle may protect the investigator against his prejudice in favour of a treatment and any consequent suggestions, but if the observer is prejudiced against a treatment or is attempting to prove that a drug is useless, it will not protect him against suggesting to the patients that both the drug and the control substance are without benefit

It would be interesting to know if the arachis oil used as a control substance by Dr Hamilton and his colleagues contained any vitamin E

PHARMACEUTICAL ADVERTISEMENTS

Sir,—It is a pity that the activities of the pharm ceutical firms in this country should be represented b such extreme views—the diatribe of Dr Elek (March 2 on the one hand and the robust and somewhat ove simplified defence by Sir Reginald Watson Jon (April 11) on the other

A large number of reputable firms undoubtedly do ex who bestow large sums of money from their resource without stipulation, and with the sole object of promotin altruistic research In so far as their income is quit often derived, to an appreciable extent, from sal under the National Health Service, this is perhap after all, a commendable form of long term nationa reinvestment We must admit, however, that there ar many other firms, not so "reputable," who are apparentl engaged, not in furthering knowledge or welfare as such but simply in exploiting the discoveries and technique of others, camouflaging otherwise standard product with new names and elegant packages, and pressing them upon the profession with the most persuasive of overture

To attempt to curb such machinations by the impo tion of further restrictive statutes is clearly undesirabl Is it, therefore, quite impossible for the manufacturers and traders' associations to implement a more determined policy by which these renegades might be induced t follow a more ethical course ?

I write, Sir, not with any authority from my medica school (lest Sir Reginald should tweak me !), but simpl as an individual who is interested in this topic

London S E 1

Roy Goulding

TREATMENT OF ADVANCED MALIGNANT DISEASE WITH RADIOTHERAPY AND A C T.H

Sir,—The letter from Mr MacGregor and Dr Lewi (April 4) prompts us to send you the following report

Our experiments on animals, performed in collaboration with Mr D E A Jones, principal physicist at the Mount Vernon Hospital, suggest that there may be some advantage in the use of cortisone or A C T H during the course of deep radiation therapy

In view of these experiments, A C T H was given to two patients with carcinoma of the bronchus who, whilst they were undergoing radical deep X ray treatment,* had developed radiation sickness Both patients showed a dramatic improvement within 48 hours Symptoms of radiation sickness had appeared early in one of these cases and became sufficiently severe to necessitate suspension of treatment with A C T H, not only did systemic symptoms disappear but dysphagia, which had previously been severe, was greatly relieved This patient completed his radical course without further trouble

In four other cases A C T H was given throughout a radical course of radiotherapy and was continued for 2 weeks after the completion of X ray treatment These patients developed no symptoms of radiation sickness, and in three cases marked clinical improvement was observed during the course of treatment

The first patient was having attacks of auricular fibrillation and invasion of the pericardium was suspected This was confirmed during a subsequent attempt at pneumonectomy The patient, however, has remained reasonably well 6 months later The second case proceeded to pneumonectomy the resected specimen showed minimal damage to irradiated normal lung tissue and microscopy revealed islets of tumour tissue which was probably not viable This patient developed a fistula and the postoperative course was complicated by secondary infection, resulting in fatal hæmorrhage from the pulmonary artery

Secondary infection also supervened in the third and fourth cases One patient died from *Pseudomonas pyocyanea* infection and this proved to be resistant to all antibiotics except polymyxin which was unsuccessful in controlling the

Letters to the Editor

THE SENIOR REGISTRAR

SIR,—At this critical period in the affairs of many senior registrars we should appreciate an opportunity to state the views of the registrars' group of the British Medical Association.

In April, 1952, we put to the Joint Committee our opinion that within a year there would be a serious crisis because, for the first time since the start of the National Health Service, large numbers of senior registrars would reach the end of their four-year tenure. A review carried out by us this month reveals the following facts :

1. In 17 of the 20 regions there are at least 279 senior registrars whose appointments are due to be terminated shortly as they are in their fourth or subsequent years. Figures for the remaining regions, including a considerable number of teaching hospitals, are not yet available ; but it is clear that the over-all total will be considerably more. The great majority of these senior registrars are employed in general medicine or surgery.

2. A survey of the advertisement columns of the medical journals has shown that during 1952 only 25 consultant posts in general medicine and 28 in general surgery were advertised ; these figures do not include the 6 posts in medicine and 5 in surgery created in late 1952 by the North-West Metropolitan Regional Board in an endeavour to solve the senior-registrar problem in their region.

We have never held the view that all senior registrars should eventually obtain consultant posts ; on the contrary, in all discussions we have agreed that competition is essential to ensure a high-quality consultant service. On the other hand it is surely reasonable to suggest that the wastage at senior-registrar level should be no more than about 25%—an ideal which should be fulfilled when the senior-registrar establishment is eventually scaled down to the agreed level so as to be related to future consultant vacancies. Last year, however, in one region between 50 and 70 well-qualified surgeons applied for each general surgical post advertised. This situation bears no relation to the fair competition we have envisaged ; it is the direct outcome of post-war expansion, for which the Ministry must bear responsibility. It is the present generation of senior registrars for whose welfare we are particularly concerned ; this is a special, non-recurring problem which needs special and immediate measures for its solution.

The following suggestions of the Registrars' Group council have been received sympathetically by the Joint Committee.

1. *The consultant service can still be expanded to the benefit of the National Health Service.*

Although the Ministry of Health have admitted their error in announcing abruptly a "freezing" of hospital establishments,[1] it is clear that they would not welcome a general expansion of the consultant service. However senior registrars are at present doing important work ; they are not just supernumerary trainees, and when establishments are cut their work will still have to be done. Consultants will be needed to replace them, and it is surely better to foresee the need and to create additional posts while the present senior registrars are available to fill them. We must point again to the action of the North-West Metropolitan Regional Board which appears to us an important contribution.

2. *The run-down to the agreed senior-registrar establishment should be slow.*

This would allow a gradual but parallel increase in the consultant service, as suggested above. We have agreed that a reduction in establishment is necessary to prevent the present problem from continuing indefinitely, but we feel that no senior-registrar appointment should be terminated before the end of the normal four-year term. It will still be possible to reduce the establishment when posts are vacated voluntarily or when the holders of posts no longer "established" reach the end of their fourth year. It is hoped that the suggestions in the next paragraph will enable suitable individuals in the latter category to continue a specialist career in another post.

3. *Any senior registrar reaching the end of his normal tenure should be allowed and encouraged to apply in open competition for his own post or for other posts in the same grade and specialty, either in his own region or elsewhere.*

It has been suggested that any senior registrar who fails to obtain a consultant post before the end of his four years in office is unlikely to be successful and that prolongation of tenure would only postpone the final disappointment. With this we would agree *in normal times* ; but, as we have mentioned, present conditions are far from normal. It is also admitted that there may be some senior registrars who for one reason or another are unlikely to attain consultant status. We believe that the method outlined above is the most equitable way of solving the present dilemma. A full selection committee is given the onus of deciding whether a man is likely to become a consultant ; if so, they will reappoint him, and if he is not reappointed it will be clear that he would be unwise to continue further. A senior registrar whose post is discontinued owing to a reduction in establishment would be able to apply for posts in the same specialty elsewhere. This plan would ensure that good potential consultants are not lost to the service purely owing to passage of time. Registrars (intermediate grade) might criticise this plan as lessening their chance of promotion. They would, of course, be eligible to compete with senior registrars for the vacant posts ; furthermore it has been agreed that there need be no limit on the duration of registrar (intermediate grade) appointments. This objection also loses substance as the shortage of registrars in the intermediate grade increases, and it is becoming difficult even to fill certain senior-registrar posts. Indeed, we would suggest that unless the Ministry encourage reapplication by senior registrars the shortage of suitable applicants will increase. We appreciate that it may be necessary to place some time-limit (say two years) on the tenure when a man is reappointed to his own post.

4. *Entry into general practice should be made easier for the ex-registrar.*

This is an immensely complicated subject. We have been pressing its importance for over three years, as there is no doubt that registrar experience is usually a positive disadvantage when application is made for a position in general practice. It is now clear that this is the main reason for the increasing shortage of junior medical staff in many hospitals. It seems to us that the manifold problems involved remain unsolved because of the sharp division that has been created between the hospital and general-practitioner services ; there appears to be no mechanism within the Ministry or even within the B.M.A. for discussing it, let alone for taking action.

The Joint Committee have been negotiating registrar affairs with the Ministry of Health for a long time ; but although the Ministry have said that they are considering the problem sympathetically, there is no indication that they realise its urgency or that they are taking steps to solve it. The figures given in this letter have been forwarded to the Joint Committee in the hope that they will be able to persuade the Ministry that the problem not only is serious but also can be solved.

R. M. FORRESTER
Late chairman.
JOHN N. WALTON
Chairman,

no member of the court had ever heard of objection being taken to such a question It was one which could properly be asked If it were held inadmissible, great difficulty might be introduced and perhaps in many cases great injustice to an innocent prisoner The appeal was dismissed

A Coroner Complains

Members of the medical profession hardly need to be reminded that coroners enjoy an independent jurisdiction to which respect may be paid and, moreover, that anything like lax certification will hardly escape comment at an inquest At a recent inquest[1] there was evidence that a woman, aged 71, had been taken to hospital because a bone had stuck in her throat At the hospital a surgeon examined her throat through a tube, he told the coroner that he saw no bone, "only a greyish black mass covered with blood" On a warning from the anæsthetist the operation was discontinued, the patient was taken back to the ward and placed in an oxygen tent Further examination was made by radiography, but the patient's condition deteriorated and death occurred two days after admission to hospital The Home Office pathologist who conducted the necropsy stated that death was due to a left pyopneumothorax caused by a wound leading from the œsophagus into the left pleural cavity

The coroner, who announced a verdict of death by misadventure, complained that the two doctors concerned had been less than cooperative One of them had made difficulties when asked for a statement, the other had wanted to send the coroner's court a statement in lieu of attendance, since he was going on holiday Worst of all, a certificate of death from natural causes had been signed, when, as the coroner observed, the history of a bone stuck in the throat should have suggested the possibility of accidental death The coroner was fully justified in pointing out that regional hospital boards, and local authorities' functions in no way affected his jurisdiction If he was asking more of the doctors than his legal authority allowed only in the High Court could his procedure be challenged

Parliament

QUESTION TIME

Flour Improvers

Viscount HINCHINGBROOKE asked the Minister of Food whether he was aware of fresh evidence that consumption of wheat flour treated with nitrogen trichloride (agene) or chlorine dioxide produces eczema and mental disturbance in allergically responsive persons, and what steps he was taking to make chemically untreated flour or bread available to such persons and to those who prefer it —Major GWILYM LLOYD GEORGE I assume that my hon friend is referring to a recently published article in a medical journal reporting a single case of allergic response to flour treated with agene or chlorine dioxide I am assured that flour which has not been treated with either of these improvers and bread made from such flour, will as hitherto be available on special request

Mr BERESFORD CRADDOCK Will the Minister not agree that bread made from wholemeal flour is much higher in nutritional value than bread made from white flour? If so, will he be good enough to inform the public widely of the beneficial effects of such flour?—Major LLOYD GEORGE I think the public have a very good idea The public also have a very keen desire to have white bread

Dr BARNETT STROSS Although the Minister has been informed that up to now there has been one single case of allergy to nitrogen trichloride has he also noted that it is expected that further cases will be found showing similar reactions? Does he not think that as we have been campaigning since 1926 to get rid of nitrogen trichloride as an improver we might have something better at long last?—Major LLOYD GEORGE This matter has been subject to careful examination for a considerable time I am very much alive to it I hope we may have an alternative which is neither of the present substance

Mr R R STOKES Is not a return to white flour much more the desire of the millers than of the general public? Why does the Minister's Department consider that it is better for people to get the right vitamins through the digestive organs of animals than from whole wheat meal?—Major LLOYD GEORGE I am not sure that I altogether accept the remark of the right hon Member about the miller because after all it is in the long run the consumer who decides what he or she should eat

Obituary

ALEXANDER MILES

M D, LL D Edin, F R C S E

Mr Alexander Miles, consulting surgeon to the Edinburgh Royal Infirmary, and the oldest resident fellow of the Royal College of Surgeons of Edinburgh, died on April 9 He had spent his whole life in Edinburgh and even at the age of 87 was still in contact with academic and medical work in the city

Born in Leith, he graduated M B at the University of Edinburgh in 1888 and in 1890 he became F R C S E The following year he was awarded the gold medal for his M D thesis and was appointed to the Syme surgical fellowship Later he became clinical tutor to A G Miller in the Edinburgh Royal Infirmary, and in 1898 he was appointed assistant surgeon He held also the post of surgeon in Leith Hospital and, following the useful and almost invariable custom in Edinburgh at that time he lectured on surgery and operative surgery in the extramural school In 1909 he was made full surgeon to the Infirmary, and he held wards for the statutory fifteen years Thereafter he was chairman of the Astley-Ainslie Rehabilitation Hospital in Edinburgh, and he carried this duty into the era of the National Health Service

After he had retired from surgical practice, he found time for much useful administrative work He served the Royal College of Surgeons of Edinburgh as secretary treasurer, and president and for fifteen years he was its representative on the General Medical Council For many years he was a member of the university court and curator of patronage, and the university conferred on him the honorary degree of LL D in 1925

The first of his important books appeared in 1904 when he collaborated with Alexis Thomson in the publication of their *Manual of Surgery*, which became immediately one of the most popular textbooks with students and graduates Forty six years later, in 1950, he was joint editor with Sir James Learmonth of the lastest edition of the volume on *Operative Surgery* His other publications included a history of prominent past surgeons of the Edinburgh school He contributed many papers to the medical journals and for a time he was editor of the *Edinburgh Medical Journal*

W J S writes "Slim in figure, Miles gave an immediate impression of quickness and alertness of body and mind, which he amply justified As a surgeon he was characterised, especially in abdominal operations by great rapidity without sacrifice of accuracy or care and he was an excellent clinical teacher with always a large following of students He was till recently so interested in the Edinburgh medical school that despite his age his death leaves a blank in the school especially of course among the older members who had been his colleagues "

Mr Miles married Miss Helen Greig, of Leith, who survives him with a daughter

RALPH PATERSON SMITH

M D Glasg D P H

Dr Paterson Smith, director of pathology at the Newcastle General Hospital, and formerly professor of pathology and bacteriology at Dalhousie University Nova Scotia, died at his home in Newcastle upon Tyne on April 7 at the age of 57

He was born in Greenock and was educated at Greenock Academy and the University of Glasgow where he graduated M B with honours in 1918 Soon afterwards he joined the R A M C and became assistant pathologist to the 4th Indian General Hospital After demobilisation he spent a short time in general practice but in 1922 he

Letters to the Editor

THE SENIOR REGISTRAR

SIR,—At this critical period in the affairs of many senior registrars we should appreciate an opportunity to state the views of the registrars' group of the British Medical Association.

In April, 1952, we put to the Joint Committee our opinion that within a year there would be a serious crisis because, for the first time since the start of the National Health Service, large numbers of senior registrars would reach the end of their four-year tenure. A review carried out by us this month reveals the following facts:

1. In 17 of the 20 regions there are at least 279 senior registrars whose appointments are due to be terminated shortly as they are in their fourth or subsequent years. Figures for the remaining regions, including a considerable number of teaching hospitals, are not yet available; but it is clear that the over-all total will be considerably more. The great majority of these senior registrars are employed in general medicine or surgery.
2. A survey of the advertisement columns of the medical journals has shown that during 1952 only 25 consultant posts in general medicine and 28 in general surgery were advertised: these figures do not include the 6 posts in medicine and 5 in surgery created in late 1952 by the North-West Metropolitan Regional Board in an endeavour to solve the senior-registrar problem in their region.

We have never held the view that all senior registrars should eventually obtain consultant posts; on the contrary, in all discussions we have agreed that competition is essential to ensure a high-quality consultant service. On the other hand it is surely reasonable to suggest that the wastage at senior-registrar level should be no more than about 25%—an ideal which should be fulfilled when the senior-registrar establishment is eventually scaled down to the agreed level so as to be related to future consultant vacancies. Last year, however, in one region between 50 and 70 well-qualified surgeons applied for each general surgical post advertised. This situation bears no relation to the fair competition we have envisaged; it is the direct outcome of post-war expansion, for which the Ministry must bear responsibility. It is the present generation of senior registrars for whose welfare we are particularly concerned; this is a special, non-recurring problem which needs special and immediate measures for its solution.

The following suggestions of the Registrars' Group council have been received sympathetically by the Joint Committee:

1. *The consultant service can still be expanded to the benefit of the National Health Service.*

Although the Ministry of Health have admitted their error in announcing abruptly a "freezing" of hospital establishments,[1] it is clear that they would not welcome a general expansion of the consultant service. However senior registrars are at present doing important work; they are not just supernumerary trainees, and when establishments are cut their work will still have to be done. Consultants will be needed to replace them, and it is surely better to foresee the need and to create additional posts while the present senior registrars are available to fill them. We must point again to the action of the North-West Metropolitan Regional Board which appears to us an important contribution.

2. *The run-down to the agreed senior-registrar establishment should be slow.*

This would allow a gradual but parallel increase in the consultant service, as suggested above. We have agreed that a reduction in establishment is necessary to prevent the present problem from continuing indefinitely, but we feel that no senior-registrar appointment should be terminated before the end of the normal four-year term. It will still be possible to reduce the establishment when posts are vacated voluntarily or when the holders of posts no longer "established" reach the end of their fourth year. It is hoped that the suggestions in the next paragraph will enable suitable individuals in the latter category to continue a specialist career in another post.

3. *Any senior registrar reaching the end of his normal tenure should be allowed and encouraged to apply in open competition for his own post or for other posts in the same grade and specialty, either in his own region or elsewhere.*

It has been suggested that any senior registrar who fails to obtain a consultant post before the end of his four years in office is unlikely to be successful and that prolongation of tenure would only postpone the final disappointment. With this we would agree *in normal times*; but, as we have mentioned, present conditions are far from normal. It is also admitted that there may be some senior registrars who for one reason or another are unlikely to attain consultant status. We believe that the method outlined above is the most equitable way of solving the present dilemma. A full selection committee is given the onus of deciding whether a man is likely to become a consultant; if so, they will reappoint him, and if he is not reappointed it will be clear that he would be unwise to continue further. A senior registrar whose post is discontinued owing to a reduction in establishment would be able to apply for posts in the same specialty elsewhere. This plan would ensure that good potential consultants are not lost to the service purely owing to passage of time. Registrars (intermediate grade) might criticise this plan as lessening their chance of promotion. They would, of course, be eligible to compete with senior registrars for the vacant posts; furthermore it has been agreed that there need be no limit on the duration of registrar (intermediate grade) appointments. This objection also loses substance as the shortage of registrars in the intermediate grade increases, and it is becoming difficult even to fill certain senior-registrar posts. Indeed, we would suggest that unless the Ministry encourage reapplication by senior registrars the shortage of suitable applicants will increase. We appreciate that it may be necessary to place some time-limit (say two years) on the tenure when a man is reappointed to his own post.

4. *Entry into general practice should be made easier for the ex-registrar.*

This is an immensely complicated subject. We have been pressing its importance for over three years, as there is no doubt that registrar experience is usually a positive disadvantage when application is made for a position in general practice. It is now clear that this is the main reason for the increasing shortage of junior medical staff in many hospitals. It seems to us that the manifold problems involved remain unsolved because of the sharp division that has been created between the hospital and general-practitioner services; there appears to be no mechanism within the Ministry or even within the B.M.A. for discussing it, let alone for taking action.

The Joint Committee have been negotiating registrar affairs with the Ministry of Health for a long time; but although the Ministry have said that they are considering the problem sympathetically, there is no indication that they realise its urgency or that they are taking steps to solve it. The figures given in this letter have been forwarded to the Joint Committee in the hope that they will be able to persuade the Ministry that the problem not only is serious but also can be solved.

R. M. FORRESTER
Late chairman.
JOHN N. WALTON
Chairman,
Registrars' Group, B.M.A.

Notes and News

HEALTH EDUCATION

IN London during the past week the World Health Organisation has been holding a regional conference on health education Attended by experts from the United Kingdom and 18 countries of Western Europe, its object has been to bring together " for mutual discussion medical administrators and persons actively engaged in health education work with the primary objective of, first, identifying the constituents of a total programme of health education of the public and, second, of planning toward expansion of health education within countries and the European region as a whole " The joint chairmen have been Dr J M Mackintosh, professor of public health at the London School of Hygiene and Tropical Medicine, and Dr Eugène Aujaleu, director of the department of social hygiene in the French ministry of public health and population On April 11 the meeting was opened by Dr N D Begg director of the W H O regional office for Europe, and the delegates were welcomed by Sir John Charles, chief medical officer, Ministry of Health, and by Professor Mackintosh who gave an introductory address Mr Iain Macleod the Minister of Health, met the delegates on April 13 The leaders of discussions were Dr John Burton, medical director of the Central Council for Health Education, Prof Pierre Delore of Lyons, Frau Magda Telber, and Prof Jaap Koekebakker, and visits were paid by delegates to hospitals, clinics, and exhibitions in London The proceedings of the conference were private

On the eve of the conference the Central Council for Health Education gave a reception at B M A House

SCOTTISH N.H S COSTS

IN Scotland the total hospital expenditure for the year ended March 31 1952, was £31 424 354, and for the executive councils £16,572 122 The report of the Comptroller and Auditor-General [1] records that examinations were undertaken at 25 hospitals where costs were high compared with the national average, and at a further 17 hospitals where " housekeeping " costs seemed high Some of the high costs were due to circumstances outside the control of the regional board, or had to be interpreted carefully in the light of variations in the volume of service provided and the general movement of prices, but it was thought that such special inquiries were nevertheless worth while Special emphasis was placed on the cost of heating which in some war time hospitals built in dispersed blocks was equivalent to £120 a year per occupied bed, but plans were already under way which would reduce this cost by a third

The pharmaceutical services for Scotland accounted for an expenditure of £5 472 758 A total of 151 000 prescription forms (1 3% of the total) were scrutinised for evidence of extravagance, but only 22 reports on prescribing of various doctors were referred for inquiry and only 2 fines were ultimately imposed In addition, the Drugs Accounts Committee, who price the prescriptions, referred back 213 individual prescriptions Of these, 89 were thought to be excessive and 4 fines were imposed

LIVING WITH TUBERCULOSIS

INSTEAD of recording that the tuberculous are constitutionally timorous, aggressive, hysteric, schizoid, obsessional, psychopathic, and whatnot (with appropriate percentages), Dr Wilmer [2] propounds that they are normal men and women who in their pretuberculous days had found life a mixed blessing but had made an average sort of adjustment to it Then the catastrophe of tuberculosis with all its implications and repercussions suddenly *befalls them* *How*, he asks, can they be helped to stand up to this additional burden ? And he makes a gallant attempt to answer this question

Just as in a sanatorium there is a basic physiological régime of abundant food fresh air, and long rest-hours, so has he set out to devise a basic psychological régime to which all patients may similarly be exposed His new patients having been given two or three weeks in which to settle down and get over their initial *bewilderment* are then gathered together in a group and given informal little talks about adjusting to tuberculosis and to sanatorium life, after which, free floating discussions are encouraged Later in the course of treatment patients with similar cultural backgrounds are invited to form discussion groups which meet from time to time and are led, if necessary, throu deeper psychiatric waters This pattern of psychother peutic action is thus partly prophylactic and partly fir aid (The occasional patient who needs more intensi personal treatment is spotted all the quicker) It is offere not as a panacea, but merely as a suggested line of action be modified according to circumstances

The three informal lectures on " Adjusting to Tuberculosis, written as they were for American patients in Americ institutions, cannot be expected to travel well Great stre is laid on the folly of patients who discharge themselve prematurely (the irregular discharge rate in the United State is higher than 50%) but this warning is, so far, less necessa in this country The sputum positive patient's infectivity played down in Great Britain, is rubbed in vigorously in th U S A (witness the habit of mask wearing among all wh come in contact with the patient—except his visitor On the other hand, the possibility that tuberculosis coul ever prove anything more than a tiresome interlude, let alor a fatal disease, to any member of his audience, is implicitl denied by Dr Wilmer (" You are bound to get well in time he seems to say, inviting, surely, the rejoinder, 'Oh yeah What about Joe who was in the next bed ? ") It seems al that the American patient does not mind being urged t enlighten his visitors about tuberculosis, and is willing on h discharge to engage in propaganda against the disease Nevertheless, in spite of these transatlantic differences i approach and emphasis, the basic idea of these talks i excellent Of his ballad, " This is Your World," some 60 lines of dialogue in vers libre between the wise doctor and th patient in varying moods, it is hard to express an opinion When read aloud by two intelligent actors to a *musica* accompaniment, it may register more than it does in col print Rather more fun is promised by the performance o his sixteen inconclusive charades, in which childhood episodes are enacted by patients, who have to improvise their lines and round off the dramatic situation when the script gives out

The book is certainly one that all sanatorium superintendents should borrow, in view of the price, and ponder

A BURNS UNIT AT GUY'S

THE Ministry of Health lately suggested that the training of surgeons should include more experience in the treatment of burns, and this was one of the reasons why a new children's burns unit has been established at Guy's Hospital [1] The unit has 12 beds—4 at Guy's for the primary treatment of severe burns, and 8 at the nearby Evelina Hospital, to which cases will be transferred for reparative surgery The Evelina beds will be part of the reconstructive and plastic unit which is already dealing with congenital deformities Mr Patrick Clarkson, who directs the burns unit, and Mr Rex Lawr , senior surgeon at the Evelina, will be in joint charge of reparative treatment and aftercare

WOOD BED-CRADLE

AT Nottingham General Hospital a wood bed cradle designed by the senior nursing staff with the aim of taking the weight of the bed clothes off the patient's feet, has proved very satisfactory This cradle shown in the accompanying figure is easy and inexpensive to make, it is put together with brass screws so that it can be easily washed and when not in use it can be clamped under the bed in a steel frame The foot of the mattress fits inside the cradle and is thus fixed so that " creeping " is prevented The sheet and blankets are placed over the end of the cradle and tucked in. If necessary an additional blanket can be placed across the end of the bed for extra warmth.

SITTING DOWN TO SURGERY

SIR,—I read with particular interest Mr. Sacks's article (April 4), having already heard the details of his method, applied to biliary surgery, from his anæsthetist colleague, Dr. N. C. Smiedt. The method is so simple that I have used it routinely in the past twelve months, at first standing on the left of the patient, but latterly sitting on an ordinary theatre stool.

The gall-bladder delivers readily through the right upper paramedian incision as soon as a little air is introduced above the liver. All the biliary organs become so superficial that the whole operation only requires short-handled instruments. Only one assistant is needed, and he has to do a minimum of retraction.

The gall-bladder can be removed almost bloodlessly by the method Mr. Sacks describes, which also makes it easy to raise the peritoneal flaps required for reperitonealising the gall-bladder bed. The cystic artery can be identified and ligated in continuity, before dividing it where it reaches the gall-bladder. One can then proceed to expose the junction of the cystic and common bile-duct and common hepatic duct.

I would confirm all that Mr. Sacks claims for his approach in cholecystectomy and choledochostomy, and would suggest that the method is well worth while even if the surgeon prefers to stand—as do certain artists, with the conviction that no worth-while painting was ever produced sitting on a stool.

I would stress particularly the ease in exposing and exploring the common bile-duct. The fingers can readily palpate the whole duct. The passage of a Bakes dilator along the duct (by the right hand) is readily controlled by the left fingers and thumb, which gently support the descending portion of the duodenum and easily palpate the dilator as it emerges through the ampulla. Should a transduodenal approach be necessary the position would be eminently suitable for it.

If from the preliminary exploration of the abdomen it appears that appendicectomy is also advisable, this is more easily done through the upper right paramedian incision in the position described, than with the patient lying flat and the surgeon on the right.

I have not yet tried the position for gastrectomy. Whilst realising the easy access to the duodenum and distal half of the stomach, I would have thought that (from its position under the left ribs) the approach to the proximal half of the stomach, and for that matter to the upper descending colon and splenic flexure, would be easier from the right side as is customary, perhaps with the aid of a sandbag under the left half of the chest.

Guildford, Surrey.   H. A. C. CHALMERS.

REMEDY FOR ANÆMIA

SIR,—I agree with Dr. George Discombe, in his letter of April 11, that the introduction of unnecessary, high-priced, polypharmaceutical mixtures encourages waste of public money, but I do not agree that the proper use of the preparation he mentions, which contains the principal known hæmopoietic substances, is either unnecessary or wasteful. Ideally, a specific nutritional deficiency should be treated with a specific nutriment, but it is rare to meet with a deficiency of one factor without depletion of others. This is particularly true in the common anæmias, since foods low in iron are for the most part low in folic acid and vitamin B_{12}. For example, Litwins and Greenwald[1] have obtained a more rapid response in hypochromic anæmia when liver extract was added to iron therapy. Smith[2] has also presented evidence of the existence in liver of still other factors than folic acid and vitamin B_{12} which account in part for its efficacy, which makes desirable the inclusion of liver fraction in therapeutic preparations.

As Dr. Discombe says, "no-one can exaggerate the importance of diagnosis in anæmia," nor can one underestimate its treatment. The use of a preparation that combines the principal substances known to be involved in hæmopoiesis would seem to be a reasonable therapeutic measure.

Bush House, Aldwych, London, W.C.2.   A. T. MENNIE.

THE FEVER NURSE

SIR,—In your leading article of April 4 you affirm your support for the present age-limit of 18 years for entrants to the nursing profession. Under the system of training in this country, where the student nurse leads an arduous and often dangerous life, lowering the age-limit would certainly be a retrograde step.

One aspect of the Russian method of training nurses, which I saw on a recent visit to Soviet hospitals and nurse-training schools, particularly impressed me. The girls begin their training *at 15 years of age and complete* a 3-year course before sitting the final examination at 18. During this period of training nurses are not allowed to work on the wards, but receive practical instruction under the supervision of their tutors, who accompany them to various hospitals in the locality. Up to 3 hours a day is spent on practical instruction. Only after passing the final examination is the nurse permitted to work on the hospital wards; and, as a result of recent directives from the ministry of health, only doctors and qualified nurses may treat patients.

London, N.10.   JOHN PREWETT.

INACCURACY IN THE LABORATORY

SIR,—The causes of the errors to which you refer in your leading article (March 7) are numerous. In addition to those mentioned two are of great importance: the calibration of glassware, especially pipettes, and the quality of the chemicals, which are purchased from several sources.

In the early days, when chemical pathologists were struggling for recognition, it was possible to set and maintain a high standard of accuracy in technique. Thus, in the first two posts I held there was time to check, and when necessary correct, the graduation of every pipette. Indeed, it was a rule that no pipette should be used until it had been checked and marked with a writing diamond. As the years passed and the work increased without a corresponding increase in staff, more and more glassware was bought—and broken—and it became impossible to check everything. Also it became increasingly difficult to teach the technicians how to do the checking. When there was only a single assistant one was able, if he stayed for several years, to impart to him virtually all one's technical knowledge. Inevitably those days have passed. Considering the pressure of work today, I marvel that the results are as good as they are.

The time factor is equally important in the testing of chemicals. In the "early days" it used to be our rule that no results should be reported until we had (*a*) mastered the technique, (*b*) made satisfactory "recovery experiments," and (*c*) established our own normal range by analysing our own bloods and those of our friends who would allow us to bleed them. Often this led to questioning the purity of the chemicals we bought. Sometimes we purified them ourselves, sometimes we enlisted the help of the firm from whom the purchase was made, and sometimes we substituted the product of another firm. If none of these expedients succeeded we refused to use the method. I estimate that for every "unit" of time nowadays allowed for a result reported, we used to spend additional time equivalent to 6 to 10 units in preparation, checking, and experimenting, for the first one or two years in which a particular method was employed. In other

Lind Bicentenary

In honour of the bicentenary of the publication of James Lind's *Treatise on the Scurvy*, the Nutrition Society is holding a conference at Edinburgh on Friday and Saturday, May 22 and 23 During the conference Surgeon Vice Admiral Sir Sheldon Dudley, F R S, will give an address on Lind, and Prof V P Sydenstricker will speak on the Impact of Vitamin Research on the Practice of Medicine Further particulars may be had from Dr C P Stewart, the department of clinical chemistry, clinical laboratory, Royal Infirmary, Edinburgh

Courses for Matrons of Homes for Old

The National Old People's Welfare Committee will hold a four month training course, beginning in October, for women wishing to take up work as matrons or assistant matrons of homes for old people The course will include six weeks' theoretical training at a centre in London four weeks' practical training in the geriatric units of London hospitals, and six weeks practical training in old people's homes Further particulars may be had from the committee, 26, Bedford Square W C 1

Medical Research in Liberia

A broad international programme of research into problems of tropical medicine and health is to be initiated immediately in Liberia, West Africa, by the Liberian Institute of the American Foundation for Tropical Medicine Dr Edward I Salisbury, president of the institute, has announced that the institute is also to provide for the education of physicians in the treatment and control of tropical diseases "Today," he declared, "graduates seeking opportunities for field work are limited almost entirely to the few large companies operating in the tropics which maintain medical departments"

Clergy and Doctors

A meeting for clergy and doctors in the Rural Deanery of Caterham is to be held on Tuesday, May 19, at 8 30 P M, in the clubroom adjoining St Andrew's Church, Coulsdon, when the Rev F. S Sinker, M B, will speak on Coöperation between Clergy and Doctors Further particulars may be had from Dr J B Gurney Smith (Royal Earlswood Institution, Redhill, Surrey), treasurer of the Union of St Luke for Communicant Anglican Doctors, or from Dr R H Hardy (1, Rolle Villas, Exmouth, South Devon) secretary of the union, who will also supply details about the union to those interested

Prizes for Medical Films

In the second competition organised by La Presse Médicale for medico surgical films, the first prize (frs 50,000) was awarded to J Frederic and R Robineaux (Paris) for their film "Cytophysiologie des phagocytes", two second prizes (frs 25,000) were awarded to M Dargent (Lyons) *for the film* 'Resection du maxillaire supérieur," and to Hofmann-Saguez (Paris) for the film 'Laryngectomie reconstitutive" Awards (frs 10 000) were also made to Lapeyssonnie (Corps de Santé colonial) for the film "La lèpre", to Baron (Paris) and Fowler (New York) *for the film* "Vertiges et lentilles prismatiques", to J Demirleau (Tunis) for the film "Traitement chirurgical des kystes hydatiques du poumon par la kystectomie", and to J T Rice Edwards (Newport, Mon) for the film "Resection of the œsophagus"

Medical Art Society

After the opening of this society's annual exhibition in London last Monday members and their guests dined together at the Café Royal Mr Bernard Adams, R P, proposing The Society, provided professional encouragement and cheerfulness Sir Philip Manson-Bahr, the president, spoke favourably of other guests and benefactors including Mr Phillip Lambe Mr Adrian Beach Mr J L Naimaster of Walkers Galleries and especially Dr A M Rackow, the hon secretary Replying for The Guests Lord Moran admitted that soon after qualifying he had forsaken medicine for a year spent among the art galleries of Italy He could not understand why men of business or affairs should grudge the 40 sittings—a mere two or three days—that would give them their one chance of posthumous fame

The society, which was founded in 1935 and now has about 130 members holds meetings monthly in the winter These include criticism by professional artists demonstrations of techniques in various media, and discussions The present exhibition, which is briefly reviewed on p 792, remains open till April 25 The hon secretary may be addressed at Flat 4 11 Hornton Street London W 8

Food and the Future

The fourth meeting in the series on this subject, which the food group of the nutrition panel of the Society of Chemical Industry is holding, will take place at the Chemical Society's rooms, Burlington House Piccadilly, London, W 1, on Wednesday, April 22, at 6 15 P M Mr W F J Cuthbertson, F R I C, and Mr P N Williams, F R I C, will speak on Synthetic Food Potentialities, and Mr Norman Wright, D SC, will summarise the whole series

view that the pituitary causes Graves's disease because it behaves like a thermostat set for an abnormally high level. The other possibility—namely, that the pituitary is unable to respond to thyroid hormone—was shown to be very unlikely in our original paper.[1]

One minor mis-statement in your editorial might stand correction. This laboratory has been well aware that repeated test doses of I^{131} in Graves's disease may by themselves influence the course of the disease.[4] No dose in excess of 40 μc. was used in the original work or in these later studies.

This work was aided by a grant from the Division of Research Grants, U.S Public Health Service, National Institutes of Health. Triiodothyronine was obtained through the courtesy of Smith, Kline, and French Co.

SIDNEY C. WERNER
HOWARD HAMILTON.

HOSPITAL COSTING

SIR,—In your annotation of March 28 the need for the measurement of quality as well as quantity is very rightly stressed. Costing analysis on a departmental basis would at least indicate the services which a hospital provides, and would show the presence or absence of the many medical diagnostic or therapeutic aids. It would not show the quality of the work done in each department, and this can only be assessed by personal examination by those with the necessary experience and knowledge. Costing analysis can never be regarded as a cure for waste and inefficiency, but only as a guide to diagnosis. When comparisons are made on a departmental basis, many of the differences arising through individual hospital circumstances can be eliminated; and when information on departmental cost is available for a whole region, variation much below or above the mean would point to the necessity for an examination of standard. Cost analysis should point to too cheap as well as too extravagant a service.

The plea for simplification is one of importance. It may be found, however, that a financial comparison of the cost of salaries and wages is simpler than one of numbers only. Numbers of staff as such are useless if some of the staff are whole-time and some are part-time, and further calculations have to be made to show total staff on a whole-time basis; by using the cost of payments to the staff as the basis for comparison this result is automatically provided. Moreover, if a comparison is needed of the use of varying grades of staff in individual hospitals, the financial aspect has to be taken into account.

Oxford.
D. M. LIVOCK.

COMPLICATION OF CAUDAL BLOCK

SIR,—Dr. Humphries's letter (April 4) about the development of high spinal analgesia following the aspiration of cerebrospinal fluid from a needle introduced into the caudal canal, prompts me to quote something I wrote in 1944.[5]

> "Once pierced, the dura must be considered able to admit any quantity of fluid introduced into the epidural space, thereby producing spinal analgesia. In one such case the writer proceeded cautiously and produced spinal analgesia up to a height of D8, with as low a volume as 11 c.c. metycaine 1%—even after the needle had been withdrawn half an inch and a further aspiration test had proved negative. Had the large dose required for caudal analgesia been injected disaster might well have supervened."

Dr. Humphries is to be congratulated upon reintroducing Silvester's method of artificial respiration. Passive movements of limb muscles have been shown to stimulate the respiratory centre by bombarding it with proprioceptor (afferent) impulses which originate in receptors in mammalian muscles. Silvester's method, which employs passive movements of the arms, is, therefore, theoretically the best method of artificial respiration. Intravenous adrenaline is the best way of combating circulatory failure in these cases—1 ml. of a 1 in 1000 solution injected very slowly in acute cases, and a 1 in 250,000 drip in circumstances where circulatory depression is less sudden in onset.

A. H. GALLEY.

INVOLVEMENT OF AUTONOMIC NERVE-FIBRES IN DIABETIC NEUROPATHY

SIR,—Dr. McPherson (March 28) calls attention to the limitations of surface-temperature recordings as an index of blood-flow in an extremity.

We would agree with him that only under the strict conditions mentioned by Fetcher et al.[1] does the surface temperature correspond well with the blood-flow. This does not mean, however, that measurements made under other conditions are of no value. Indeed, Fetcher et al. state elsewhere[2] that if only gross changes in blood-flow are to be measured then lower heat-loss rates than the 240 kg. cal./hr./m.^{2} mentioned by Dr. McPherson may be adequate. It is clear, therefore, that Dr. Martin's results (March 21) are not invalidated by Dr. McPherson's considerations. The majority of the surface-temperature changes in the foot recorded by Dr. Martin are certainly sufficient to constitute a satisfactory indication of change in blood-flow.

Lewis, in the sentence presumably referred to, wrote: "Perhaps the most reliable method of gauging the state of the blood flow to a resting limb *clinically* is to estimate its surface temperature" [our italics]. The venous occlusion plethysmograph, with which he obtained results embodied in many of his papers, he regarded as too cumbersome to employ in the routine work of the clinic.[3] The same objection was made to the calorimeter, although, as Cooper et al.[4] recently showed, this method will follow large changes in blood-flow with considerable accuracy.

It is possible that the heat-flow meter described by Hatfield,[5] while of comparable simplicity, may be more reliable than the thermocouple for clinical assessment of blood-flow in an extremity. Most workers would agree, of course, that estimations of blood-flow calculated from surface-temperature and heat-loss, singly or together, are less accurate than measurements of actual flow.

H. S. BURRY
Satra fellows.

SIR,—I agree with Dr. McPherson that measurements of total blood-flow by means of a plethysmograph would have been of great value in my investigation of vasomotor tone in diabetic neuropathy, but unfortunately I had no plethysmograph at my disposal.

I should like to point out, however, that the changes in skin-temperature that were recorded were never supposed to be true indices of total blood-flow or even accurate estimations of skin-flow, as it is well known that there is no linear relationship between blood-flow and surface-temperature. In the investigation reported (March 21) changes in skin-temperature were simply reported as an indication of vasomotor activity—i.e., of the presence of vasoconstriction (about 20°C) or vasodilatation (above 32°C)—and even the workers quoted by Dr. McPherson do not deny the reliability of thermocouples for this purpose. As far as my conclusions are concerned, it appears to be immaterial whether below 20°C the blood-flow may be reduced further without a corresponding drop in the skin-temperature,

capillaries in the choroid plexus and the pressure of the ventricular fluid produces a fluid in Donnan equilibrium with the blood This theory has been discussed by Mestrezat and F Fremont-Smith. Mestrezat showed that a collodion sac left in the peritoneal cavity gradually comes to contain a fluid with a composition similar to that of the C.S F.

Donnan's equilibrium is reached when two solutions are separated by a membrane with very small stomata, allowing diffusion of the smaller but not of the larger molecules The smaller molecules migrate to the side of the lower osmotic pressure, until the osmotic pressure is equal on both sides of the membrane Thus if there is blood on one side and distilled water on the other, after a time there will be more sodium chloride in the water than in the blood-serum but much less protein However, Donnan's law does not hold exactly for the C.S.F For instance, the alkalinity of the C S.F is somewhat lower than that of the blood Magnesium is present in higher concentration and sugar in lower concentration, in the C.S F. than in blood-serum Moreover, the C.S.F. changes considerably in constitution during its migration from the ventricles to the subarachnoid space of the lumbar region

It is true that spinal fluid is produced below the level of complete occlusion of the spinal canal (for instance, by spinal tumour), but this fluid has a composition very different from that of the normal C.S.F., as Nonne and Froin have shown Electrophoresis of the C.S.F permits refined analysis of its components, and shows that it contains the same proteins as blood, but in different proportions—the globulins being rather scarce in the normal C.S.F There is also a special component, consisting of very small albumin molecules, which appears as a precursor during electrophoresis, examples of which have been collected by my assistant, Dr J Steger.

We use strips of paper for electrophoresis. We stain the proteins and measure the intensity of the stain photoelectrically This method has shown that the small albumin molecule is almost absent in the blood serum though relatively concentrated in the ventricular fluid It diminishes by degrees during the migration of the fluid to the cisternæ and to the lumbar region.

This molecule is completely absent from the thick yellow fluid below a complete spinal blockage of the subarachnoid space. It is also absent from the fluid of gliomatous cysts, which seems to indicate that it is not produced by the glia. So this small-molecule albumin seems to be further evidence for a specific function of the choroid plexus

Lina Stern and others have believed the C S.F to have a nutritional function for the nervous system They assumed that all substances passing from the blood to the brain must pass the C.S.F barrier *This brings us to* the perivascular spaces, first discovered in pathological conditions by Virchow and Robin These aroused the special interest of Cushing who always thought that they acted like a lymphatic space, evacuating waste-products from the nerve cells into the subarachnoid space Cushing induced me to investigate these perivascular spaces, and with Percival Bailey I spent a considerable time in studying them. We found that they exist only round the larger vessels of the brain, round the capillaries there is only a little connective tissue In certain pathological conditions—e g inflammation and œdema—perivascular spaces can be demonstrated round the smaller vessels In certain types of meningitis like that caused by torula the fungus invades the perivascular spaces, which distend enormously, but we have not found in these conditions any perivascular space round the capillaries, nor are they visible in cases of tumour sealing the subarachnoid space. All this proves that there cannot be very much fluid discharged from the perivascular spaces into the subarachnoid space

Folders and Arrowood have shown the enormo importance for the C.S F. of the osmotic pressure of t blood; and Weed used this method to investigate t fluid transport in the perivascular spaces He was al to show that only by increasing the osmotic pressure the blood to a high level could C S.F be forced from t subarachnoid space into the perivascular spaces

We used this method to study experimentally the chan of the perivascular sheaths in animals injecting a hyperto solution of saline into one carotid and a hypotonic solut into the other The animal was killed by adding formalin the solutions and the skull was opened immediately and t brain studied We found that on the side of the hypoto solution the brain was swollen the subarachnoid spaces emp the perivascular spaces collapsed, but the spaces arou the pia described by His, were dilated In contrast, on t side of the hypertonic fluid the vessels were dilated, the su arachnoid spaces and the perivascular spaces were dilate and the tissue of the brain was shrunk But nowhere d we find any spaces round the capillaries

It thus seems unlikely that there is any circulation spinal fluid accompanying arteries which are breakin up into the capillaries or leaking alongside the veins i the subarachnoid spaces, as has been assumed by som authors without experimental proof The substance exchanged between the brain tissue and the vessels pa only through the vessel wall and the surrounding gli tissue

Still, a good deal of exchange is possible between th C S.F and the nervous system though it is not by wa of the perivascular spaces It takes place simply b diffusion

One can show this experimentally by introducing a Bi schowsky solution into the subarachnoid spaces The silve penetrates into the depth of the brain, precipitating in parall Liesegang layers. The importance of diffusion has also bee shown by the experiments of Goldman and Spath, wh injected trypan-blue into the subarachnoid spaces This dy spreads diffusely through the nervous system, and though i certainly accumulates in macrophages round the vessels, th is merely the result of active phagocytosis We were ab to demonstrate this by putting glass capillaries filled wi trypan-blue into the brain This time the dye escaped fro the opening of the capillary the surrounding tissue wa stained, and macrophages transported the dye to the vess in the neighbourhood

What is the volume of spinal fluid produced in a day and absorbed in a day? Flexner and Winter found that cats with an average weight of 3 kg and a brain weight of 22 g would produce about 12 ml of spinal fluid a day Haug and Haug stated that man needs from 3 to 6½ hours in order to produce 40–65 ml of spinal fluid In three-quarters of an hour, 10 ml of spinal fluid is produced Similar results were obtained by Riser and Massermann in France If a needle is left in the subarachnoid space for some hours 3–5 ml of spinal fluid is produced hourly The absorption of the spinal fluid has been studied by Falkenheim and Naunyn who injected normal saline under different pressures They were able to show that the speed of absorption depends on the fluid pressure Fog Rasch and Stuerup got the same results with experiments on animals Folders and Arrowood who studied this question in human beings, found that up to 2000 ml of fluid at a pressure of 50 cm of water can be injected in twenty four hours into the subarachnoid space

Woodehoff and I have tried to develop a clinical test based on these experiments We measured the spinal pressure of a patient lying quietly on his side As soon as his spinal fluid pressure was constant we removed 5 ml by puncturing the rubber tube connecting the needle with the manometer We observed the drop of pressure and waited until it had risen to the original level Using this method we found that 5 ml is usually replaced within twenty minutes In a second experiment we injected 5 ml of spinal fluid slowly into the rubber tube The spinal fluid pressure rose and we again waited until it had dropped to the original level This infection. The fourth patient was found at necropsy to have widespread secondaries in the pancreas and liver, but the immediate cause of death was pneumonitis due in part to *Staphylococcus aureus*, resistant to all antibiotics except penicillin, which had no clinical effect even in enormous doses.

It is common experience that latent infection may be exacerbated in patients undergoing treatment by these hormones for any condition, and, in the animal experiments referred to above, the animals submitted to radiation and cortisone injections suffered much more seriously from secondary infection than the control animals without cortisone. It is felt that A.C.T.H. was in part responsible for the infection which supervened in two of the above patients. In order to avoid this known complication of prolonged hormone therapy, the period of A.C.T.H. administration was covered by injections of streptomycin twice weekly and penicillin daily. It is probable that this prolonged prophylactic course of antibiotics was unhelpful and even predisposed to the development of resistant organisms.

Investigations are proceeding to evaluate the possible use of A.C.T.H. in combination with radiotherapy in the treatment of carcinoma of the lung, but it is obvious that the risk of so treating a lung which may well be heavily infected at the start of treatment must receive very serious consideration. These cases and further animal experiments will be reported more fully in a later communication.

Harefield Hospital, Middlesex. L. E. HOUGHTON.
Middlesex Hospital, London, W.1. J. B. WALTER.

RENAL DUCTS OF BELLINI

SIR,—Dr. Duran-Jorda states, in his article last week, that he is sceptical of accepting the existence of openings of the ducts of Bellini, and is considering the possibility that in the normal kidney the urine is dialysed through a pelvic epithelium and not excreted by the ducts of Bellini into the renal pelvis. The views of other histologists on this should prove interesting.

It is quite easy to make a cast of the ducts of Bellini in man by injecting 'Neoprene' (latex) up the ureter, thus proving irrefutably that openings of the ducts into the calyses do exist. The ducts of Bellini are also demonstrated from time to time in retrograde pyelograms—the phenomenon of pyelotubular back-flow. Pyelotubular back-flow, though not as common as pyelovenous back-flow, is well known to urologists and radiologists. When it occurs, it clearly demonstrates the continuity of the ducts of Bellini with the renal calyces.

Photographs of pyelotubular back-flow, and of a neoprene cast of a kidney showing tufts of pyelotubular back-flow into the ducts of Bellini, are included in an article by me on pyelorenal back-flow.[1] These should give Dr. Duran-Jorda some proof that, whatever the state in the newborn, openings of the ducts of Bellini into the renal calyces certainly do exist in the adult.

Edinburgh. JAMES A. ROSS.

KERNICTERUS

SIR,—Dr. Govan and Dr. Scott (March 28) ascribe kernicterus to brain lesions from anoxia at the time of birth. Another explanation seems possible to me.

Kernicterus usually makes its appearance a few days after birth, and might be due to the withdrawal of an inhibiting or neutralising substance or substances present in utero but unavailable to the infant after birth. This substance might originate in the placenta, and by its presence prevent kernicterus in the unborn infant. The withdrawal of this factor after birth might permit the development of kernicterus within a few days.

On this hypothesis placental extract was administered to a group of infants with hæmolytic disease by intramuscular injection of 1 ml. morning and evening from birth to five or six days of age—that is, until the danger period for the development of kernicterus was probably over. The results were as follows:

Group	*Transfusions*		*Kernicterus*	
	Exchange	*Simple*	*No. of cases*	*Incidence (%)*
Control (48 cases)	13	35	8	16·66
Treated (57 cases)	35	22	1	1·07

While these results would appear to warrant further investigation, they may be fortuitous or related to the somewhat higher rate of exchange transfusion in the treated than in the control group. This investigation continues, but meanwhile it would be interesting to have the opinions of other workers in this field.

National Maternity Hospital, Dublin. COLMAN M. SAUNDERS
Director of Pædiatrics.

HUGH OWEN THOMAS

SIR,—I am writing a new Life of Hugh Owen Thomas, together with a revised edition of his collected works. Any assistance in this task would be welcomed; in particular, I am anxious to have access to previously unpublished material. Letters or documents relating to any aspect of Thomas's private or professional life, or to the history of the family, will be carefully handled and returned to the owners as soon as possible.

10, Harley Street, London, W.1. DAVID LE VAY.

A LONG-ACTING LOCAL ANÆSTHETIC

MR J. I. M. JONES, D.SC., writes from the research department of Crookes Laboratories Ltd.: "Your annotation of March 28 implies that 'Efocaine' remains stable for about three months. This view is evidently based on the paper by Ansbro and his colleagues to which you refer. Later results show that for practical purposes the preparation is stable for an indefinite period."

Medicine and the Law

A Doctor's Cross-examination

APPEALS from convictions for murder are often brought with insubstantial prospect of success. The recent appeal in R. *v.* Holmes[1]; was based on a complaint that a question to a medical witness was wrongly allowed. The appellant, after making what his own counsel described as a savage and frenzied attack on his landlady, went to the police and said he wanted to give himself up for murder; he wrote out a detailed account of his actions. At the trial a doctor, called by the defence, was asked in cross-examination whether, in his opinion, such conduct, immediately after the murder, would indicate that Holmes knew that what he was doing was unlawful—i.e., wrong in law, within the meaning of the McNaughten rules. The witness answered "Yes." Counsel cited judicial dicta to the effect that medical opinion must never usurp the function of the jury in finding the facts; the witness, he contended, could not be asked what was in the accused person's mind when the homicidal assault was committed. The question and answer were inadmissible.

The Lord Chief Justice interrupted counsel's argument with the suggestion that the appeal seemed to raise a merely academic question. The doctors on both sides now agreed that Holmes was certifiably insane; he would be dealt with under the Trial of Lunatics Act, 1883, and kept in custody during Her Majesty's pleasure. Counsel replied that a long line of authorities laid it down that medical men, however eminent, could not be allowed to take on the functions of a jury by giving an opinion on the question which the jury had to answer.

The Lord Chief Justice observed that, whatever fine distinctions had been drawn in some of the cases cited, the blood circulation Within certain limits the air-bubble within the cranial cavity will behave as if there were no skull around it Observations on a patient with a rather large hydrocephalus taught us that he felt comfortable only at a certain atmospheric pressure level He would develop a headache as soon as the pressure rose above this level or as soon as it dropped below it One instance caused a relative hypertension of this air bubble, the other a relative hypotension In fact this was the first observation we made of the clinical effects of a hypotension, and it led later to our becoming interested in aliquorrhœa

---

[1] Ross, J. A. *Brit. J. Urol.* 1952, 24, 27.

[1] *Times*, March 31.

Another factor which causes an increase in the C S F is lack of oxygen (e g, at high altitudes) Forbes and Wolff have already reported such increases in animals It can be abolished immediately by the breathing of oxygen These effects of high altitude on the brain are important when people with wounds of the head are transported by air Before the second world war, French army physicians observed large prolapses of the brain in soldiers who had been wounded in Morocco and transported to France by air We now know the explanation the brain is blown out of the skull, partly through lack of oxygen, and partly because air has entered the ventricles and is expanding in the high altitude These factors must be taken into consideration when people with wounds of the brain are transported by air The danger can be avoided if the patient is transported in a pressurised cabin, or if the air is carefully removed from his ventricles before transportation, and he breathes oxygen during the flight

THE PIA-ARACHNOID

In discussing the physiology and pathology of the C S F circulation we cannot ignore the pathology of the membranes lining the subarachnoid space Even the normal membranes behave neither like rubber nor like glass they are semipermeable and allow of diffusion of proteins and other substances from the blood and the brain There are many conditions in which this diffusion is enormously increased—particularly in all cases of true inflammation Here the spinal fluid assumes a composition which resembles that of the blood serum There are several other conditions in which there is no leucocytic exudation—for instance in what Roessle and Eppinger would call serous inflammation, and what Schuermann called dysoria Dysoria means that the stomata of the vessels are too wide, and so too much protein is able to leave the vascular channels I believe that we need not bother to decide whether dysoria really means the beginning of an inflammation or not It is more interesting to know in which conditions we find dysoria, and what are its consequences

The oldest known example of dysoria is the dysfunction of the meninges which causes the enormous increase of proteins in the spinal fluid below a spinal tumour and in its vicinity The fact that even the spinal fluid above a tumour has a raised protein content shows that obstruction of flow cannot be the only cause Guillain and Barré have shown that the composition of the spinal fluid in polyneuritis is very similar to that below an obstruction Here again we have dysoria as one of the most important parts of the syndrome Another syndrome in which dysoria evidently plays a role is aliquorrhœa What spinal fluid we are able to draw off in aliquorrhœa is high in proteins This is due to the greater difference in pressure between the blood circulation and the spinal-fluid spaces, which causes engorgement of the vessels and hence widening of their endothelial stomata We have observed a fourth condition associated with dysoria—namely a chronic change following a mild meningitis

A patient had been wounded in the right temporal lobe by a shell fragment For some time he had been suffering from a small abscess of the temporal lobe which drained well and which was cured (as necropsy later proved) During his surgical treatment signs of meningitis developed which were controlled by intensive peroral sulphonamide treatment As the raised cell count in his spinal fluid fell, he began to complain about terrible pains in his legs and back Lumbar puncture showed that the proteins in the C S F increased from week to week, while the Queckenstedt test showed no blocking We even tested the patency of the spinal fluid system by introducing a small air-bubble which passed into the ventricles without difficulty Finally lumbar puncture drained some fluid which immediately clotted in the tube Further lumbar punctures did not produce any more fluid Eventually the patient developed flaccid paralysis and segmental sensory disturbances of his legs, indicating a cauda equina lesion He acquired pressure sores and urinary infection, and died from septicæmia Necropsy revealed that the spinal fluid in the C S F spaces had clotted just as it had done in the tube Cauda equina and spinal cord were wrapped in a gelatinous mass which was in the process of organisation by fibroblasts

I believe that this process of colloid exudation followed by fibroblastic organisation is very common, many instances of increased protein in the spinal fluid after lesions of the brain or inflammation of the meninges may be associated with it Of course the enormous rise of protein content can only happen when large areas of the meninges show such a pathological change But localised changes of this kind may be the cause of the adhesion and fibroblastic organisation which go under such different names in neurology as arachnoiditis adhesiva circumscripta, arachnoiditis serosa cystica, pachymeningitis, and dural hygroma I propose that we should regard all these disorders as meningopathies and distinguish them from the recognised inflammatory disorders which are accompanied by leucocytic infiltration

* * *

The facts discussed here have been collected and contributed by great physicians of all nations Knowledge of these disturbances is indispensable for the clinician, yet there are still many riddles to be solved, and we of the older generation have left enough for the younger ones to do

EFFECT OF ISONIAZID ON TUBERCULOUS LESIONS OF THE KIDNEYS

JOHN C DICK
M D Glasg, F R F P S

GLASGOW UNIVERSITY LECTURER IN PATHOLOGY AT STOBHILL HOSPITAL, SENIOR PATHOLOGIST, GLASGOW NORTHERN GROUP OF HOSPITALS

THE use of isoniazid in the treatment of tuberculosis has produced some contradictory results The first intimations of its clinical effects (Robitzek and Selikoff 1952, Monaldi 1952, Klee 1952, Morland 1952, Sita Lumsden 1952, Bartley 1952, and others) were full of hope in view of its dramatic results after even a short period of treatment The preliminary report of the M R C Tuberculosis Chemotherapy Trials Committee (Medical Research Council 1952) showed that, after a 3-month course of treatment in pulmonary tuberculosis the results with isoniazid were comparable to those with streptomycin and *p* aminosalicylic acid (P A S) showing greater gain in weight and general condition, though slightly less effect in reducing fever and erythrocyte sedimentation rate (E S R), and in sputum conversion and radiographic improvement, but a warning was given that drug resistant tubercle bacilli appeared quickly (as had already been found in vitro) On similar lines Joiner et al (1932) found that isoniazid alone had a beneficial effect in some cases of pulmonary tuberculosis in the first 3–6 weeks, but thereafter the improvement was not maintained, and ultimately deterioration ensued associated with the excretion of resistant strains of tubercle bacilli, whereas isoniazid combined with strep took his D.P.H., and while holding a Medical Research Council appointment carried out an investigation into enteric carriers. The following year he became demonstrator in pathology at Durham University, and assistant pathologist in the Royal Victoria Infirmary, Newcastle.

In 1927, at the age of 32, he went to Dalhousie University as professor of pathology and bacteriology and provincial pathologist for Nova Scotia. In the following year he was awarded his M.D. with honours and also the Bellahouston gold medal. During his years in Canada his advice was widely sought on medicolegal problems in all the Maritime Provinces. He was a founder fellow of the College of American Pathologists; and examiner in pathology to the Dominion Medical Council of Canada and the Canadian College of Physicians and Surgeons. Apart from his abiding interest in medicolegal pathology, he was for many years a member of the American Association of Geographic Pathology and he was also a member of the International Association for Dental Research. Three years ago he returned to this country as consultant pathologist to the Newcastle General Hospital, and he administered his department with his customary energy and enthusiasm until his death.

A colleague writes: "Paterson Smith was an excellent teacher, and his students often had the highest average standing in pathology examinations, in which they had to compete with men from all other Canadian universities. As a man he was courteous and unselfish; he was endowed with an enormous fund of energy which was evident to all those who visited his department. His careful work in various branches of pathology was published in a series of admirable papers, and his writings were not without influence on the medical teaching of his day. His introduction of the term 'lobular hyperplasia' into the classification of diseases of the breast did much to dispel confusion."

Dr. Paterson Smith leaves a widow and five sons, one of whom is a medical student at Durham University.

EDWARD SCOTT WORTHINGTON

K.C.V.O., C.B., C.M.G., C.I.E., M.D. Toronto

Sir Edward Worthington, formerly an assistant director-general of Army Medical Services, and physician to the late Duke of Connaught, died in London on April 5, at the age of 76.

He received his medical education at Trinity University, Toronto, and he held the degree of M.D. Toronto. In 1899, after coming to this country, he took the Conjoint qualification and in the following year he joined the R.A.M.C. He served in the South African war from 1899 to 1902. He was appointed medical officer on the staff of the Duke of Connaught for the opening of the Union of South Africa Parliament in 1910, and he was again M.O. to the Duke of Connaught while he was governor-general of Canada from 1911 to 1914. He was knighted in 1913.

For his services in France from 1914 till 1916 he was mentioned in despatches and "brought to notice for valuable services rendered." He also received the brevet of colonel, the American Distinguished Service Medal, the Order of Leopold (4th class), and the Belgian Croix de Guerre. He was appointed C.M.G. in 1915. In 1917 he rejoined the staff of the Duke of Connaught, and in 1918 he was appointed C.B., and the following year created K.C.V.O. He was with the Duke at the opening of the Princes' Council in India in 1920, and in 1921 he was appointed C.I.E. Sir Edward was deputy assistant director-general and assistant director-general at the War Office from 1917 to 1922. He was appointed K.H.P. in 1922 and he retired in 1926.

EUGEN POLLAK

M.D. Vienna

Dr. Pollak's death on April 9 will be keenly felt by his colleagues in Manchester, his adopted city, where he had lived since 1939 and where he was university lecturer in neuropathology. He was one of that small band, the really widely informed and accomplished neuropathologists. At the Neurological Institute in Vienna he had been a pupil of Marburg, Obersteiner, and Erdheim, as well as of Wagner-Jauregg, who had first encouraged him in neurology. He had a large number of important papers to his credit chiefly about the degenerative and chronic infections of the nervous system.

Dr. Pollak came from a Vienna that had already lost the glitter, the panache of the royalist times which he had known, but still was magnetic in a medical sense. Everybody went to Vienna sooner or later to listen to one authority or other. There was no branch of medicine that the Viennese school had not richly adorned. The pilgrimage was made the more attractive by the charm of the surroundings as well as the good humour and tolerance of the Austrian character. Dr. Pollak himself had good humour in abundance, a remarkable memory, and a wide and, what is more, a critical knowledge of the medical personalities of Central Europe. Toleration he kept within bounds. He was unable to speak of the Vienna of the last war without rancour, since he was ashamed of the way that so many of his countrymen had succumbed to the Nazi influence. He was deeply grieved by the murder during the war of his sister to whom he was so devoted. He was therefore insulted rather than flattered when offered the directorship of his old laboratory four or five years ago.

He was a lonely figure in many ways, proud and reticent about himself, but as fine an example as one could have of a courageous man of principle, the victim of political misconduct and worse. But this was not all. Until his illness he was always excellent company, and he was a wit whose comments on medical or world affairs were always eagerly listened to by his friends in the university. Moreover he was deeply interested in music and, as an ardent admirer of the Vienna Philharmonic Orchestra and the friend of musicians, he had much to tell that was refreshing and original. In the old days before the first world war Manchester had had a liberal-minded German colony of cultured business men who were responsible for a great deal of that city's supposed addiction to the arts as well as to the mechanical crafts. Pollak would have been instantly at home with them, they had the same wide interests, the same artistic passions. That colony of course has long been gone, but Pollak rekindled memories of those times.

I have spoken mainly of Pollak as a man whose company I and many others will sorely miss. He wrote very little after he came to England, preferring to accumulate material and make histological preparations in a way few, if any, could surpass. But then, before he had time to put together the fruits of his labours, illness took hold of him. We shall long remember his witty personality, his intelligence, his courage, his honesty, his independence.

Mrs. Pollak died young. He is survived by a married daughter in Vancouver, B.C.

HOFFMAN, EUGENE, M.D. Prague, F.R.C.S.: consultant thoracic surgeon, Newcastle regional thoracic service.

SMITH, W. H., M.B. Lond., D.M.R.D.: consultant radiologist, Plymouth clinical area.

East Anglian Regional Hospital Board:

DAS, J. B., M.B. Madras: surgical registrar, E. Suffolk and Ipswich Hospital.

MCCARTHY, AGNES, M.B. Lond., D.A.: anæsthetic registrar, Peterborough Memorial Hospital.

MCCONNELL, JOAN, B.A., M.B. Camb.: registrar in psychiatry, St. Andrew's Mental Hospital.

MONRO, R. S., B.A., M.B. Camb., F.R.C.S.: consultant surgeon, Ipswich hospital group.

Appointed Factory Doctors:

CLARKE, R. W., M.B.E., L.R.C.P.: Rushden, Northamptonshire.

RILEY, E. F., M.B. Birm.: [illegible] shire.

SIM, C. G., M.A., M.B. Durh.: [illegible] erland.

STEWART, D. L., M.B. Aberd. [illegible]

The Hospital for Sick Children, Great Ormond Street, London:

HOYTE, F. C., M.B. Lond.: house-surgeon, orthopædic and plastic departments.

LUDER, JOSEPH, M.D. Lond., M.R.C.P., D.C.H.: medical registrar and pathologist.

PALLOT, DOREEN, M.B. Lond., D.A.: junior resident anæsthetist.

RICHARDSON, F. L., M.B. Birm.: house-physician.

SIMPKISS, M. J., M.B. Birm.: asst. medical registrar.

Western Regional Hospital Board, Scotland:

BROWN, R. C., M.B. Glasg., D.A.: asst. anæsthetist, Western Infirmary, Glasgow.

GERRARD, BARBARA, M.B. Lond., D.A.: asst. anæsthetist, Victoria Infirmary and Hairmyres Hospital, E. Kilbride.

SNODGRASS, MARJORY, M.B. Glasg., F.R.F.P.S., D.O.M.S.: asst. ophthalmologist, Glasgow Eye Infirmary.

nothing like this appearance round the lesions was found Further, no such appearance was present in specimens from cases after treatment with streptomycin either alone or combined with P A S

Microscopic Lesions

AFTER LESS THAN A MONTH'S TREATMENT WITH ISONIAZID AND NO PREVIOUS CHEMOTHERAPY (CASES 1–4)

In the kidneys from these cases the edges of the cavities showed appearances quite distinct from those of corresponding stages of tuberculous granulation tissue in specimens from untreated cases In the latter the acute stage showed a fairly broad reactive zone at the caseating edge, in which the kidney tissue was infiltrated with lymphocytes and epithelioid cells, with or without giant-cell follicles, and in which the interstitial tissue was undergoing early caseation and the parenchymatous elements were becoming disorganised and necrotic the whole process was avascular

In specimens after treatment with isoniazid (figs 6 and 7) the reactive zone was much narrower and more definite, there was much less cellular reaction, both epithelioid cells and lymphocytes being relatively scanty, the interstitial tissue was not caseating but showed vacuoles near the caseated edge, while the remainder looked healthy, though œdematous, and contained numerous small blood-vessels, newly formed and intensely congested, and the tubules were no longer necrotic or broken up but well formed right up to the caseated edge, with their epithelial cells clear and distinct Thus, not only had the caseating process stopped but the surrounding tissue was reacting strongly and even causing absorption of some of the caseated material

In somewhat more chronic areas of the granulation tissue (fig 8) there was the usual palisading of epithelioid cells, but in place of formation of fibrous tissue and thickening of the edge of the cavity there was a looseness in which epithelioid cells were more indefinite than usual, the interstitial tissue was œdematous and vacuolated, and fibrous tissue was completely absent Occasionally there were thinning and absorption of old caseous material near the margin (fig 9), and young blood-vessels were found, often running close to the caseous area (figs 8 and 9) In densely fibrosed parts of the cavity walls (fig 10) epithelioid cells again showed palisading at the edges, with lack of collagen and with vacuolation in the caseation, suggesting absorption of the necrotic material—i e, almost a reversal of the process by which it was formed The dense fibrous tissue was broken up and traversed by newly formed capillary blood-vessels

Similar abnormalities in the tuberculous lesions were found in the mucosa of calyx, pelvis, and ureter Thus there appeared to be a cessation of activity in acute caseation, with vacuolation in its deep layer (fig 11), accompanied by vascularity of the mucosa and reduplication of epithelium in nearby tubules In older lesions the main features were œdema and vacuolation in place of fibrosis between the palisaded epithelioid cells, and vascularity deep to the edge of the granulation tissue (cf figs 8 and 10)

Apart from the "open" tuberculous lesions—i e, those in cavity, calyx, pelvis, &c, leading to bacilluria and causing changes in the pyelogram—the other small and large lesions scattered throughout the parenchyma showed slight but definite changes from those in specimens from controls and untreated cases The individual epithelioid follicles (fig 12) were numerous and "loose," the epithelioid cells showed no tendency to orient themselves, nor was there any fibrous tissue in or surrounding the follicle, even though fibrosis and round celled infiltration were conspicuous in the surrounding

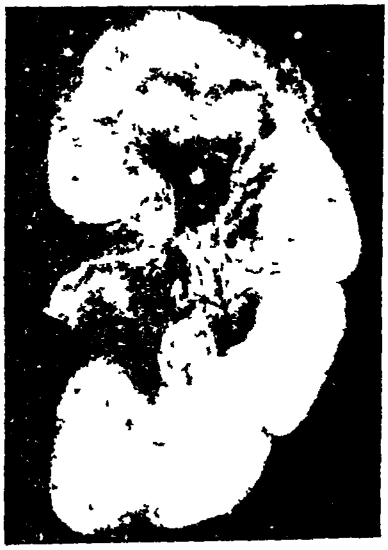

Fig 4 (case 6)—After 3 months treatment with isoniazid extensive ulcerocavernous tuberculosis of upper pole with congestion calyces and ureters with nodules of tuberculosis congestion and large areas of hæmorrhage and a few isolated follicles with surrounding congestion spreading down into middle zone (× 3/5)

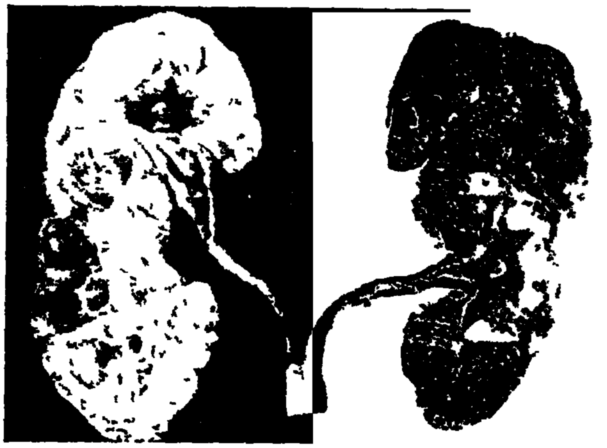

Fig 5 (case 8)—After 48 days treatment with isoniazid, kidney with double ureter Recent irregular ulcerocavernous lesion at upper pole with congestion and hæmorrhages, also in ureter from this pole, and extensive diffuse disease in parenchyma round it, and middle-zone and lower-pole lesions, drained by lower ureter, more chronic, with slight patchy congestion (× 4/5)

LEGENDS TO ILLUSTRATIONS

Fig 6 (case 1)—Edge of acute cavity showing prominent tubules in very vascular œdematous granulation tissue leading to narrow line of poorly defined epithelioid cells, beyond which is caseated material, edge of which shows fissures and a few vacuoles between epithelioid cells, but no fibrosis (× 100)

Fig 7 (case 1)—Edge of cavity, not quite so acute as fig 6, showing tubules and granulation tissue as before Broader line of epithelioid cells still no spread of caseation or fibrosis, but more vacuolation between cells (× 100)

Fig 8 (case 2)—Edge of more chronic cavity Zone of epithelioid cells fairly broad but with vacuolation between and no fibrosis interrupted by ingrowth of group of capillaries Instead of layer of fibrosis outside there is infiltration of lymphocytes and young capillaries no fibrosis in parenchyma beyond (× 100)

Fig 9 (case 1)—Edge of chronic cavity below, with old caseation at top Across centre there is a zone of lightening of caseation near epithelioid zone which is composed of indefinite cells, shows no fibrosis and is being infiltrated by young capillaries from below (× 100)

Fig 10 (case 4)—Edge of densely fibrosed cavity The fibrosis has lost its orientation by being infiltrated with young capillaries and by superficial layer losing its collagen to form indefinite epithelioid cells caseation beyond is showing vacuolation (× 100)

Fig 11 (case 1)—Mucosa of calyx showing increased vascularity and prominent tubules with epithelioid cells, vacuolation, and indefinite caseation at surface (× 100)

Fig 12 (case 4)—Isolated tubercle in kidney parenchyma. Epithelioid and giant cells very ill defined and no fibrosis within or immediately round follicle (× 100)

Fig 13 (case 4)—In the centre there is an indefinite area of eosinophilic material extensively infiltrated by young congested capillaries —probably an absorbed follicle (× 100) prevent draughts. The cradle does not interfere with the patient using a bed-table. The chairman of the hospital writes that many patients who have been in bed for a long time have been grateful for having their feet free. "The medical staff," he adds, "find these cradles an excellent elbow-rest when stopping to talk to a patient. In fact, some ward sisters call them 'doctors' detainers.'"

Any hospital management committee that is interested can obtain a sketch showing dimensions and details of construction from the Secretary, Nottingham no. 1 Hospital Management Committee, *c/o* the General Hospital, Nottingham.

THE MEDICAL DIRECTORY

THE names of untraceable medical practitioners, mainly with overseas qualifications, having been omitted, *The Medical Directory 1953*[1] contains 3116 fewer names and 97 fewer pages than it did last year. There are no new features, and the price remains the same.

TO COMPLETE THE SET

THE Harveian Librarian of the Royal College of Physicians of London (Prof. E. C. Dodds, F.R.S.) is seeking a copy of the Harveian oration for 1849, which is the only volume missing from the college's set of these lectures. The following particulars of the oration are given in the catalogue of the Army Medical Library:

> BADELEY (Joh. Carr.) Oratio ex Harveii Instituto in ædibus Collegii Regalis Medicorum habita pridie calend. Julii, A.D. 1849. 20pp. 8°. London: J. Churchill, 1849.

Professor Dodds asks anyone who can help him in the quest to write to him at the college, Pall Mall East, S.W.1.

University of Liverpool

At recent examinations the following were successful:

Ph.D. in the Faculty of Medicine.—E. S. Jones.

M.B., Ch.B., final examination, part II.—J. D. Agnew, J. A. Barlow, A. G. Bowers, M. J. A. Britten, N. T. Burnett, B. J. Charlick, R. W. Coffee, J. S. Comaish, J. R. Cope, G. W. Danger, K. S. Davies, R. J. G. Downie, Florence M. Duckenfield, D. P. Duffield, T. R. Evans, R. Finn, J. G. Foley, D. Gardner, Anne M. Godfrey, D. H. Goldsmith, Mary Gregson, Patricia O. Grundy, W. B. Hanley, P. A. Harrison, J. W. Hill, H. B. Hilton, E. J. M. Hopkins, C. L. Imison, R. A. Johnson, P. L. Jones, P. King, J. B. Laine, V. Leach, C. L. Levene, G. Lloyd, B. A. Lowe, Joan K. McCann, Anne D. University of Glasgow

Mr. W. A. Mackey has been appointed to the St. Mungo chair of surgery (Royal Infirmary) in succession to Prof. J. A. G. Burton, who retires at the end of the session.

Mr. Mackey graduated M.B. with honours at the University of Glasgow in 1927 when he was awarded the Brunton prize as the most distinguished graduate in medicine of his year. For three years he acted as assistant in pathology under Sir Robert Muir, F.R.S., and later he became an assistant
under Prof. Archibald Young. With
surgery he spent a year in the United
F.R.F.P.S. and the following year F.R.C.S.E.
late war Mr. Mackey was in command o
university O.T.C., and during the war he
lieut.-colonel in charge of the surgical divisions of various hospitals in Europe and the Middle East. On his return from war service he became assistant in surgery under Prof. C. F. W. Illingworth, and last year he was appointed a surgeon in charge of wards at the Southern General Hospital, Glasgow. Mr. Mackey is a member of the council of the Association of Surgeons of Great Britain and Ireland, a member of the International Surgical Society, and a founder member of the European Society of Angeiology. He has published papers on the surgical treatment of arterial hypertension and of Banti's syndrome.

Royal College of Surgeons of England

At a meeting of the council held on April 9, with Sir Cecil Wakeley, the president, in the chair, Prof. Reynaldo dos Santos of Lisbon was admitted to the honorary fellowship. The following were elected to the fellowship without examination as being medical practitioners of at least 20 years' standing: Mr. W. E. Tucker (Bermuda), Prof. F. Davies (Sheffield), Mr. J. Dobson (Wigan), Mr. R. Scot Skirving (Sydney), Mr A. E. Coates (Melbourne).

The Jacksonian prize for 1952 was awarded to Mr. John Borrie, and a certificate of honourable mention was awarded to Mr. Rodney Smith. The council selected the following as the subject for the Jacksonian prize for 1954: Melanomas and Melanosis.

Diplomas were granted jointly with the Royal College of Physicians to the following:

D. Phys. Med.—L. S. Bain, E. E. Bullock, A. B. Coyer, J. A. Joyce, Stephen Mattingly, A. P. H. Randle, Dorothy J. Roth, R. A. Shaddick, G. O. Storey.

D.O.—Judith MacA. Brown, Rahmat Ullah Chowdhary, Khurshed Jehangir Dastur, J. M. Heaton, Savitri Itchhaporia, B. R. Jones, Mary A. C. Jones, A. T. Karsgaard, Mithlesh Kumar Mehra, John Moss, Mohamed Nawaz, C. I. Phillips, Ahmad Samad, Jagjit Singh, J. R. van der Merwe, B. I. Williams, Thomas Wilson.

D.T.M. & H.—Imteyazuddin Ahmad, Anwar-ul-Islam, Timothy Awuku-Asabre, Abdu Rasaki Oladeinde Bakare, S. A. Biggart, E. B. Bright, G. H. Burgess, Carmel Cachia, J. E. Cranswick, R. A. Davis, Silas Rofine Amu De
C. H. Gurd, Shiekh Mohammed
Hendow, C. S. Heymann, Jasmine
W. N. Laing, A. R. T. Lundie, A. D.
Supperamaniam Madesan, M. C.
Dattatraya Ramadwar, Saville Pau
H. G. Skinner, G. J. Stott, Glad
Vethanayagam, Shyamlal Vyas, M.
Ross Woodward.

D.L.O.—P. J. Damato.

D.I.H.—P. H. Nash.

D.M.R.T.—R. Finney.

Royal College of Physicians of London

Prof. R. A. McCance, F.R.S., will deliver the Humphry Davy Rolleston lectures at the college, Pall Mall East, S.W.1, on Tuesday and Thursday, May 5 and 7, at 5 P.M. The subject of the lectures is Overnutrition and Undernutrition.

Sanderson-Wells Lecture

Prof. E. C. Dodds, F.R.S., will deliver this lecture on May 20, at 4.30 P.M., at the Middlesex Hospital, London, W.1. The title of the lecture will be Chemicals and Food, A Reconsideration.

Society of Chiropodists

The annual convention of this society will be held in London from May 7 to 9. Further particulars may be had from the secretary of the society, 21, Cavendish Square, W.1.

Society of Chemical Industry

At a meeting of the crop-protection panel of the agriculture group, to be held at the Chemical Society, Burlington House, London, W.1, on April 20, at 5.30 P.M., Mr. J. R. Booer, PH.D., will discuss Organo-mercurial Fungicides.

British Association

The annual meeting of the association will be held this year in Liverpool from Sept. 2 to 9 under the presidency of Sir Edward Appleton, F.R.S.

Convalescence for the Elderly

Seapark House, Greenisland, co. Antrim, was opened on April 10 by Mr. Iain Macleod, Minister of Health for England and Wales, as a convalescent home for elderly patients discharged from geriatric units who no longer need hospital care but are not yet fit to look after themselves in their own homes or in residential homes. The house was bought and equipped with money allocated from a gift of £1 million to the people of Britain from the people of South Africa. It belongs to the National Corporation for the Care of Old People, and is the fourth of its sort—the other three are at Englefield Green, Stanmore, and Glasgow. The new home will be maintained jointly by the Northern Ireland Hospitals Authority and by welfare authorities.

NORMAL AND PATHOLOGICAL PHYSIOLOGY OF THE CEREBROSPINAL FLUID CIRCULATION *

GEORGES SCHALTENBRAND
M.D.

PROFESSOR OF NEUROLOGY OF THE UNIVERSITY OF WUERZBURG, GERMANY

FOR millions of years the nervous system of the vertebrates has been irrigated by the cerebrospinal fluid. Probably the C.S.F. took the place of the water of the ocean in which the first living beings originated. But whereas the blood has been known since remote antiquity, Galen, in the second century after Christ, said that the cavities of the brain are inhabited by a gas-like *spiritus animalis*, and this opinion survived until modern times. Varolio, in 1591, was the first to describe a fluid in these spaces, but his statements were not believed; and even Albert von Haller and Romberg (1820) held that during life the cavities of the brain are filled not by fluid but by a humid gas. It was François Magendie who, at the beginning of the last century, convinced his contemporaries of the existence of the C.S.F. The circulation of the blood was discovered by William Harvey in 1628, but only during the last forty years has the circulation of the C.S.F. been gradually brought to light by the wonderful researches of Quincke and of Cushing, and his pupils Dandy and Weed. It was Cushing who, in his Cameron lecture, first spoke of the "third circulation."

DEVELOPMENT

The C.S.F. system, like the lymphatic system, forms a short circuit between the arterial and the venous circulations.

To understand the C.S.F. system we must start with its ontogenesis and phylogenesis. The entire nervous system develops from an ectodermal groove which closes itself to a tube and sinks below the surface of the body. The interior of this tube is the *Anlage* of our ventricular system. The tube is sealed at both ends but the dorsal wall of the medullary tube, in the cephalic part, gets thinner in several places. The surrounding meningeal tissue increases in vascularity in these places and pushes the membrane-like thin part of the medullary tube into the ventricles. This is the beginning of the choroid plexus. During the further development of the brain the plexus carefully follows the changes in its shape. The roof-plate of the fourth ventricle forms membranous sacs which extend around the cerebellum and the brain-stem; from these derive the fluid spaces in the leptomeninges, which in adult mammals surround the entire nervous system. These fluid spaces lie between a double connective-tissue sheet—the pia mater, which is, as it were, soldered to the nervous system, and the arachnoid, which is in direct contact with the dura mater everywhere. The external C.S.F. communicates with the internal C.S.F. via the foramen of Magendie and the foramina of Luschka of the fourth ventricle. A third foramen, the foramen of Elze, has recently been discovered in the roof plate of the fourth ventricle in some individuals.

This macro-anatomy was elucidated by the classical investigations of Key and Retzius in the last century. These workers emphasised the connection of the C.S.F. with the venous system by way of the arachnoid villi, the largest of which are known as pacchionian granulations. Arachnoid villi can be found around the entire nervous system in the neighbourhood of the veins, and are especially numerous along the sinus longitudinalis. The arachnoid villi consist of very soft connective tissue which can easily be distinguished from the dense dural tissue. Only a very thin endothelial layer separates them from the blood in the veins. Some of them seem to end near a complicated system of tubes running parallel to the sinus and ending in it. This tubular system evidently contains not blood but C.S.F.; and if the dura is scratched in this region during an operation, spinal fluid will leak out.

The most important organ in the ventricles is clearly the choroid plexus. It is an extension of the meninges, covered by a single layer of cuboid epithelial cells. These have the typical structure of glandular cells, with many mitochondria, big Golgi bodies, small vacuoles, large nuclei, and one or more nucleoli. They also have cilia, producing a *bordure en brosse*. Under the microscope one can see how the living cell occasionally extends through the *bordure en brosse* fingerlike processes which seem to evacuate their contents into the surrounding fluid. Lack of oxygen causes the cells to disintegrate very rapidly into a foamy structure, when they produce a picture which—most likely erroneously—has been taken as evidence of secretory function. The choroid plexus is innervated by a dense network of nerves as has been demonstrated by Stoehr and Clarke.

CIRCULATION OF C.S.F.

Quincke, the inventor of lumbar puncture, first assumed that there was a C.S.F. circulation from the ventricles into the subarachnoid spaces, and his theory was proved by the studies of Cushing, Dandy, Weed, and Wegefarth.

Dandy produced artificial hydrocephalus by blocking the escape channels of the C.S.F. Weed injected an isotonic solution of iron ammonium citrate and iron potassium cyanide into the subarachnoid spaces, killing the animals several hours later by injecting formalin and hydrochloride acid into the arteries. Prussian-blue formed wherever Weed's fluid had penetrated, and could be seen in microscopical sections, both in the villi and the venous system, as well as in the sheaths of the cranial and spinal nerves. The circulatory flow of the C.S.F. was demonstrated with X ray in the living organism by Wustmann, who injected 'Diodrast' into the subarachnoid spaces of animals.

There is a strong suspicion that the choroid plexus plays an essential part in the production of the C.S.F. If the plexus is exposed by operation in the ventricles of an animal one can observe under the binocular microscope the formation of fluid lakes around this organ. Putnam and I were able to show that fluorescein, injected into the veins, leaves the choroid plexus in the form of thick green clouds. But we also observed that green colour leaked out from all the vessels of the subarachnoid space. There is a possibility that the ependyma, too, participates in the formation of C.S.F., for we find C.S.F. in the embryonic ventricles before the choroid plexus has formed.

Some authors have held that the choroid plexus has an absorptive function; and in fact Askanazy found iron in the epithelium after hæmorrhage into the ventricular system. The conditions are easily reproduced experimentally. Moreover, fat and lipoids are increased in the cells of the choroid plexus after the injection of erythrocytes into the ventricles. Ma Wen Chao, Chen Ju Lin, and myself were able to prove that this is a non-specific response of the plexus, similar to an inflammatory response. Any injection into the C.S.F. (for instance, of air or trypan-blue) will cause the same changes—swelling of the connective tissue, and increase of the lipoids and of neutral fat in the epithelial cells. These changes persist for several days.

FORMATION AND CONSTITUTION

There are two theories about the production of C.S.F.—the theory of secretion and the theory of ultrafiltration. According to the theory of ultrafiltration, or dialysis, the production of the C.S.F. is a physical phenomenon in which the difference between the pressure in the which were undergoing disintegration and were surrounded by intensely congested and dilated blood-vessels, while the tubular epithelium in the neighbourhood was often reduplicated and apparently rejuvenating

---

* Lecture delivered at the National Hospital, Queen Square, London, on Oct. 31, 1952.

Apart possibly from the fibrosed caseous lesions in case 7, the previous shortened courses of therapy with streptomycin + P A S left no histological changes in the tuberculous lesions The other changes present were all referable to the immediately preceding isoniazid therapy

In case 9, after 180 g of streptomycin $1^{1}/_{2}$–2 years previously, most of the cavity walls (and these formed by far the greatest amount of kidney tissue still remaining in both organs) showed reactivated but modified acute caseation, as in cases 5 and 6 (cf fig 14) Interest was focused more, however, on parts which had been densely fibrosed by the previous streptomycin therapy Fig 26 shows such a part caseated material intermingled with a few red blood-cells lay on a densely fibrosed wall, but there were no signs of reawakened tuberculous activity at the margin, the fibrosis, however, seemed to be softening, a tubule showed more active epithelium than was found in post-streptomycin fibrosis and was apparently pushing its way through, and several minute blood-vessels, surrounded by slight round-cell infiltration, were found Among the isolated lesions scattered throughout the parenchyma small loose epithelioid follicles (fig 12) were present, sometimes embedded in areas of chronic pyelonephritis, and were surrounded by numerous young blood-vessels and occasionally by frank hæmorrhage Of the lesions fibrosed by the previous courses of streptomycin the collagen had become homogenised (fig 27) and invaded by numerous congested blood-vessels, and tubules were prominent A variation is shown in fig 28, where there was a small hæmorrhage in the centre of a homogeneous focus, with numerous capillaries and slight surrounding infiltration A further stage of absorption in a smaller lesion is shown in fig 29

Secondary Infection

Only two of the nine specimens of kidney showed no evidence of secondary pyogenic infection This is in keeping with the previous finding (Dick 1953) that the great majority of "surgical" tuberculous kidneys show evidence of secondary pyogenic infection by the time of operation Even in connection with one of the uninfected kidneys the ureter showed subacute and chronic pyogenic inflammation In four of the specimens there were both acute and chronic stages of pyogenic infection, and in the other three there were only scattered foci of chronic pyogenic inflammation, these last three were from patients who had received the full 3-month course of isoniazid The fact that acute pyogenic infection was present in four specimens from patients under treatment with isoniazid confirmed that on some pyogenic organisms isoniazid did not exert an antibacterial effect

Care was taken throughout this investigation to ensure that changes due to these secondary infections were not attributed to the isoniazid, this was especially important as regards the increased vascularity, but it is believed that the fields chosen for the illustrations do show that there is a great increase in vascularity quite apart from any possible mild pyogenic inflammation in these areas Also, the renal changes due to isoniazid were found just as clearly in specimens with no secondary pyogenic changes

Discussion

The effects of isoniazid on the tuberculous lesions in human kidneys consisted of an extraordinary series of changes involving absorption of caseation, vascularisation of the edges of lesions, inactivation of epithelioid cells, and complete lack of surrounding fibrosis, forming a process quite unlike the natural defensive mechanism of the untreated host to tuberculous invasion Although the specimens examined were few, the extent of cavity walls and the number of lesions studied were very large The main changes were so consistent that it seemed reasonable to accept these changes as the fundamental effects of the isoniazid treatment Further details of any or all of the changes may still await discovery in different tissues of the body Here each of these changes is considered as regards not only the renal lesion but also its importance in the treatment of tuberculosis in general

ABSORPTION OF CASEATION

Though the absorption of caseation is the first effect of isoniazid chosen for discussion, the clinical evidence of very rapid subjective improvement in the patient and the regular fall in temperature indicate that the drug has a very early and effective action in checking the toxæmia by direct action against the tubercle bacilli (as has been shown in vitro)

This absorption is shown in acute lesions in figs 6, 11, 16, and 22 For its accomplishment it depends on the other features, especially the increased vascularity and lack of fibrosis at the margins of the lesions In open lesions, however, *the full effect of isoniazid appeared* to diminish after long-continued administration of isoniazid alone (fig 14, and cases 5, 6, 8, and 9) In the more chronic lesions, there is definite evidence of its beginning after a month's treatment with the drug, in figs 8 and 9, and absorption of the homogeneous material into which fibrous tissue can be converted by the action of isoniazid is found after longer administration (figs 18 and 27–29) Clinical corroboration of this is provided in pulmonary cases by the diminution in volume of sputum The volume of necrotic material being absorbed and the time the patient takes for this process may be the determining factors in the fall or lack of fall in the E S R, a feature which has varied considerably in clinical reports

This effect of isoniazid is obviously of great importance and places the drug in the forefront of those effective against tuberculosis From the evidence of these kidneys the absorption was optimal from the 2nd to 4th week of treatment in acute lesions and appeared to continue throughout the course in chronic lesions Complete absorption of lesions is the aim of all treatment, and isoniazid gives great promise of accomplishing this in recent acute lesions

---

LEGENDS TO ILLUSTRATIONS

Fig 22 (case 7)—Wall of small cavity at tip of calyx, showing regenerating epithelium, under which is one indefinite epithelioid follicle becoming absorbed No fibrosis (× 100)

Fig 23 (case 7)—Epithelioid follicle, possibly with some central caseation becoming vacuolated, with no evidence of fibrosis, and with rejuvenating kidney tubules round it. (× 100)

Fig 24 (case 7)—Several fibrosed epithelioid follicles, becoming vacuolated and infiltrated with round cells centrally and peripherally This is not the picture of renewed tuberculous activity nor of normal process of fibrosis but appears to be an early stage of absorption (× 100)

Fig 25 (case 8)—A follicle, near a calyx with poorly formed epithelioid cells, central vacuolation and a ring of intensely congested capillaries. Epithelium in neighbouring tubules shows some reduplication. (× 100)

Fig 26 (case 9)—A cavity wall with dense old fibrosis (partly due to previous streptomycin and P.A.S) but now showing some loosening with young capillaries and a tubule pushing through *There is no evidence of tuberculous activity* (× 100)

Fig 27 (case 9)—An old densely fibrosed lesion with fibrosis hyalinised but now being broken up and infiltrated by congested blood vessels (× 100)

Fig 28 (case 9)—Another hyalinised old lesion with hæmorrhage and vacuolation centrally, and congestion and round-cell infiltration round it. (× 100)

Fig 29 (case 9)—Small old hyalinised lesion with no epithelioid cells slight central vacuolation and congestion and round-cell infiltration round it. (× 100)

happened in about twelve minutes. Reimers has confirmed our results, which indicate that the daily production of C.S.F. is some 100–250 ml.

EXCESS AND DEFICIENCY

I have already mentioned the changes in the rate of production mechanically produced by alteration of the osmotic pressure of the blood. But the clinician knows conditions in which the rate of production of the C.S.F. is changed because of other factors. Quincke has described symptoms caused by abnormal production of C.S.F.: headache and choked disc developed, and Quincke called this condition meningitis serosa. Unfortunately this term is now being used by many writers for inflammatory conditions, and therefore I propose for the non-inflammatory type the name *liquorrhœa*. This condition can imitate a tumour; it is often secondary to a focal infection: Molhant and McAlpine found it after infections of the nasal sinuses, and Symonds saw it after otitis. Liquorrhœa can also be caused reflexly by lumbar puncture, or by concussion of the brain. In these cases we sometimes find the proteins in the lumbar fluid diminished so that it resembles ventricular fluid in its composition.

Aliquorrhœa is the opposite to liquorrhœa. Here the production of spinal fluid ceases. This has been discussed in the French literature for twenty years under the name of hypotension of the spinal fluid, or ventricular collapse. The clinical symptoms have a remarkable resemblance to those of increased C.S.F. pressure. The patient complains of severe headache, and we find retraction of the neck, slowing of the pulse-rate, nausea, dizziness, and buzzing in the ears. One is inclined to think of increased intracranial pressure, but the optic discs are not choked and the patient complains of increased headache when he tries to sit up or to stand up. Lumbar puncture is dry: we do not get a drop of spinal fluid. After removing the needle's pilot, we even hear a noise because air is aspired into the subarachnoid spaces. Only by aspiration do we succeed in getting a few drops of yellowish spinal fluid. Its protein content is increased. All the disagreeable symptoms disappear immediately when we fill up the subarachnoid space carefully and slowly with warm Ringer solution until a normal pressure has been reached. This helps for a day or two, but then the old symptoms return and we sometimes have to give repeated injections before they finally go. Repeated lumbar punctures show nicely how the pressure gradually increases and the composition of the spinal fluid gradually becomes normal.

I have seen aliquorrhœa develop spontaneously in young women. There are some similarities with acute anuria in nephritis, and I believe that there is a reversible disturbance of the function of the choroid plexus, possibly of vasomotor origin. In other cases the diminution of C.S.F. pressure is probably due to a general dehydration. This type of aliquorrhœa can be regarded as an aspect of osmotic change. We often see aliquorrhœa as a result of lumbar puncture; it seems as if the diminution of C.S.F. pressure is too strong a stimulus for the choroid plexus, and causes a sudden stop of spinal fluid production. Leriche, Mahoudeau, and Vincent have described aliquorrhœa after head injuries and operations on the brain. In some of these cases there must be an additional cause—namely, atrophy of the choroid plexus. This is particularly true in old cases of hydrocephalus due to obliteration of the fourth ventricle by tumour. When the tumour is removed the choroid plexus is unable to resume normal activity. It is my opinion that aliquorrhœa is one—if not the most important—cause of pachymeningitis hæmorrhagica, chronic subdural hæmatoma, and even of cerebral hæmorrhage. The reduced volume of C.S.F. must be compensated by abnormal engorgement of the vascular system; and, when the vessels are diseased or otherwise damaged, this causes hæmorrhage. Old people, especially, are disposed to such accidents because in old age, as Zalka has shown, the choroid plexus atrophies. In operations for subdural hæmatoma it is striking to see how deeply the brain is sunk into the cranial cavity, showing no tendency to expand after the evacuation of the blood-clot. Only when the ventricular system is filled with saline solution does the brain resume its normal shape.

ABSORPTION

Are there any disturbances of absorption of the spinal fluid? So far no facts are known suggesting any nervous regulation of absorption. It seems that the absorption largely depends on the pressure of the spinal fluid; and of course the size of the stomata leading into veins and lymphatic channels is of importance. Increased absorption follows many conditions with increased C.S.F. pressure, particularly meningitis. Some results of meningitis are apt to interfere with absorption, particularly obliteration of the channels leading into the blood and lymphatic system, occasioned by the particular composition of the spinal fluid. Not only corpuscular elements but also colloidal clots are liable to obliterate these stomata. In addition, all spinal fluids with a high protein content have a higher viscosity than normal spinal fluid, and so have less tendency to be absorbed. A similar effect is caused by hæmorrhages into the subarachnoid space. High viscosity may also be responsible for the surprising observation that at levels below spinal tumours absorption is practically zero. The same holds true for the polyneuritis of Guillain and Barré: in this condition a somewhat reduced absorption of spinal fluid is associated with increased C.S.F. pressure, and this may be due to the high protein content of the spinal fluid, which resembles the spinal fluid below a tumour.

In 1783 the Scots anatomist Alexander Monro, of Edinburgh, published a paper on the structure and function of the nervous system in which he pointed out that the skull and bony spinal canal are a rigid container; in consequence he believed that the blood content of the brain would always be the same. George Kellie, an English physician, supported Monro's assumption on the strength of necropsy findings on hanged and frozen people. But both these authors ignored the rôle of the spinal fluid. Cushing took this into consideration and gave a new formula to the Monro-Kellie doctrine as we may fairly call it. He said that the sum of the volume of the brain plus the volume of the spinal fluid and the volume of the blood within the skull must be constant. Increase of the volume of one of these must automatically cause reduction of the volume of one or both of the others. As the spinal fluid can escape to some extent into the spinal canal, some change in the blood volume of the brain is possible; and since we know that the width of the arteries and capillaries of the brain depends on nerve impulses, there is not much left of the original Monro-Kellie doctrine by Cushing's modification. The possibility of compensation through escape of the spinal fluid, however, holds true only for small and rapid changes in the volume of the brain. Slower and bigger changes must be compensated for by increased or diminished production or absorption of spinal fluid.

The Monro-Kellie theory can be well studied by introducing a fourth substance into the C.S.F.—namely air, which can be seen on X-ray examination.

We have made studies on these lines in a pressure chamber, in order to find a method of improving the absorption of air after encephalography. We were able to prove that once there is an air-bubble in the ventricles its size depends on pressure in the external atmosphere. The influence of the atmospheric pressure in the interior of the cranial cavity is exerted through

VASCULARISATION OF EDGES OF LESIONS

One of the features of untreated tuberculous lesions is the lack of blood-vessels within the lesion itself and their comparative scarcity in the immediate vicinity The action of the tubercle bacillus seems to be almost specifically directed against them Thus, when numerous young blood-vessels appear round a tuberculous lesion and infiltrate into the very substance of the lesion, it can be interpreted as a sign that the tuberculosis is no longer active and healing is taking place Young blood vessels in a congested state are shown especially in figs 6, 14, 16–18, 25, and 27 (mostly after the full 3 months' treatment) but were found in all the lesions They may be accompanied by minute hæmorrhages into the surrounding tissues or occasionally by macroscopic hæmorrhages into or around the lesions These hæmorrhages into small regressing follicles were reported by Berblinger (1952) in his necropsy findings in a case of pulmonary tuberculosis after 45 days' treatment with isoniazid No such increased vascularity is found after treatment with streptomycin alone or with streptomycin and P A S This vascularity with occasional hæmorrhages also seems to occur in pulmonary cases under treatment with isoniazid as evinced by the occurrence of hæmoptysis (Borthwick 1952) It provides the mechanism for absorption of the caseation and the homogenised material from old fibrosis Further, it occurs to a lesser extent in old fibrous lesions (figs 10 and 26), and if this aspect of the action of isoniazid can be developed it may provide a means of attacking organisms embedded in chronic lesions, though it cannot hope to lead to complete physical cure of such lesions

Though this feature of the action of isoniazid is almost entirely beneficial, three dangers must be pointed out (1) if the organisms become resistant to isoniazid, vascularisation may open up surrounding tissues, causing local extension of the lesion, (2) some organisms may possibly enter the blood-stream and be disseminated throughout the body (especially back to the lungs) and cause reinfection by resistant strains, and (3) vascularisation may increase the size of a lesion and possibly bring on unexpected symptoms—e g, in meningitis fits may be caused by a tuberculoma in the brain It may be possible to minimise this risk by giving a short course of streptomycin and P A S before administering isoniazid This vascularity may be the cause of the primary exacerbation of symptoms mentioned by Bartley (1952)

INACTIVATION OF EPITHELIOID CELLS AND LACK OF FIBROSIS

In the great majority of untreated tuberculous lesions epithelioid cells play a most important rôle (Cameron 1952) They are present, often in a most characteristic palisaded arrangement (Marshall 1953), round the edges of all but the most acute and very chronic caseated lesions, and they are the principal cells scattered throughout the so called "epithelioid" lesions, in each case being very closely associated with the development of fibrosis in and round the lesion as it becomes more chronic, or softening into caseation if it becomes more acute Though the appearance of epithelioid cells and the development of fibrosis in and round the tuberculous lesions are due to separate constituents of the tubercle bacilli (Blacklock 1951, Cameron 1952) it is too early to differentiate the effects of isoniazid on these processes and for the present they will be discussed together The most important effect of streptomycin with or without P A S (in addition to checking the spread of acute caseation) was an intensification of the fibrosis both throughout and round all the tuberculous lesions

Isoniazid does not further this natural defence reaction, it even puts this whole process out of action apparently by liquidating so far as it can the epithelioid cells Where the acute caseating process was stopped abruptly (figs 6 and 11), there was no zone of epithelioid cells, or, where caseation had been not quite so acute (fig 7), the cells were few and even more indefinite than usual, and no fibrosis was found Where a more chronic area of caseation already had established a well palisaded row of epithelioid cells, the zone was much looser and vacuolated, the cells were more indistinct, and no collagen was seen (fig 8) the fibrosis which normally would be developing deep to the epithelioid zone was completely absent In still more chronic lesions (fig 9) absorption of caseation near the epithelioid zone was found and the epithelioid and fibrous zones again showed loss of collagen, very indistinct epithelioid cells and infiltration by young capillaries In a still denser fibrous wall (fig 10) there were breaking up of the fibrosis by young capillaries, vacuolation towards the caseated surface, and the apparent conversion of the fibrous tissue cells into an irregular layer of indistinct epithelioid cells —a complete reversal of the normal tuberculous process Even where the process of fibrosis had been consolidated previously by streptomycin (fig 26), isoniazid appeared to be having some effect in vascularising and softening the fibrosis

This effect of isoniazid has been dealt with in considerable detail as regards cavity walls because of the far-reaching implications involved, if this is the true interpretation of the histological appearances The *British Medical Journal* (1952) suggested that a satisfactory drug for the treatment of tuberculosis should be able, among other properties, to vascularise chronic fibrous tissue and to enable the chemotherapeutic action to reach bacilli deeply embedded in old lesions Isoniazid appears to have considerable possibilities in this direction

Isoniazid has the same effect in causing disintegration of the epithelioid cells and preventing the development of fibrosis in isolated parenchymatous "epithelioid" lesions (figs 22–25) Where the lesion had already fibrosed completely, a most unexpected series of events took place the fibrous tissue became converted to an eosinophilic and very finely granular or almost homogeneous substance (fig 29), which became surrounded by large congested blood-vessels (figs 18 and 27), with some round cell infiltration, sometimes showing a small central hæmorrhage (figs 18 and 28), and became gradually absorbed (fig 13) No epithelioid cells appeared throughout the whole process

There has been considerable difficulty in fitting the radiological appearance to the clinical in patients under treatment with isoniazid The realisation of this lack of fibrosis, even absorption of fibrous tissue, in the healing of tuberculous lesions after treatment with isoniazid suggests that reassessment of the criteria of radiological improvement may be required

Another important consideration arising from this effect on fibrosis applies to the treatment of tuberculous meningitis Isoniazid may prove to be the drug required to cause absorption of the exudate rather than fibrosis and thus to prevent the development of hydrocephalus

RESISTANCE TO ISONIAZID

In a few highly selected cases the proportion in which the tubercle bacilli develop resistance to isoniazid would be misleading A true indication of the number of cases under treatment with isoniazid alone which developed drug-resistant bacilli could be reached only by a large scale investigation as in the M R C's second interim report on pulmonary cases (Medical Research Council 1953) and from this it emerged that the figure was 35% after 3 months' treatment This seems to explain the regressive histological appearances in the open lesions in cases 5, 6 8, and 9 and indicates most emphatically that isoniazid should not be used by itself for longer than 6 weeks But longer treatment is required for the satisfactory effects in isolated lesions Fortunately, the same M R C report showed that the development of tomycin gave continued improvement. Further, in a trial of isoniazid in renal tuberculosis, Borthwick (1952) requested permission to stop treating the cases with isoniazid alone, because the clinical results were disappointing.

The results in laboratory animals are also somewhat equivocal.

In mice Bernstein et al. (1952) reported that isoniazid was far superior to streptomycin or to P.A.S. in preventing infection, even when treatment was delayed after inoculation. In guinea-pigs and rabbits, however, Steenken and Wolinsky (1952) found that, though isoniazid very successfully suppressed experimental tuberculosis, the infection was not eliminated. In intra-corneal tuberculosis of mice Knox et al. (1952) found that isoniazid controlled the development of infection, but that, when isoniazid was withdrawn after 4 weeks, typical lesions developed. Goulding and Robson (1952) confirmed this and showed that streptomycin and isoniazid given together controlled the disease much more distinctly, whereas in rabbits isoniazid alone had a greater suppressive action than had streptomycin.

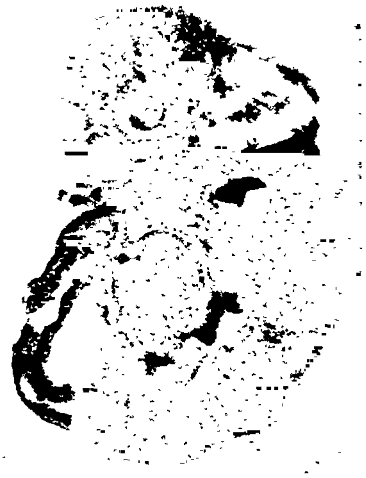

Fig. 1 (untreated case)—Small kidney with large ulcerocavernous lesion in lower part of upper pole, showing irregular ulceration round tips of other calyces; small nodules of tuberculosis in pelvic and ureteric mucosæ; and collections of white nodules in bands across medulla and cortex in middle zone and lower pole. ($\times {}^{2}/_{3}$)

A further development is the study of the action of isoniazid on tubercle bacilli and macrophages in tissue culture.

Suter (1952) and Mackaness and Smith (1952) have shown that, even with fully bacteriostatic concentrations of both streptomycin and isoniazid, the intracellular bacilli remained viable for at least seven days, though isoniazid was equally active against intracellular bacilli and those in liquid medium.

These animal and in-vitro experiments, however, do not explain the complexities of the clinical findings.

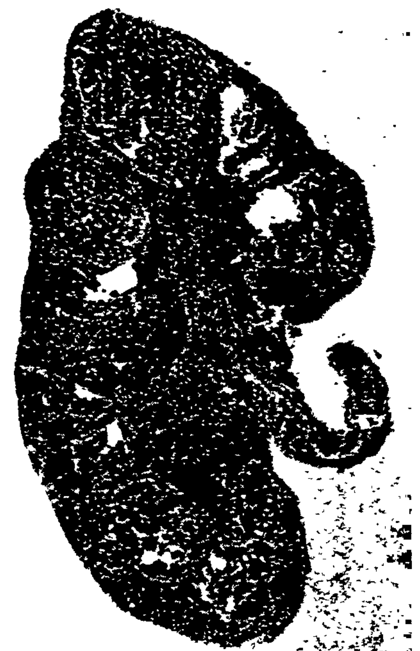

Fig. 2 (untreated case)—Considerably enlarged kidney showing ulcerocavernous lesions in all areas, largest in upper pole, smallest in middle zone; and lining of cavities consisting of hard cracked greyish-white caseated material with irregular white tuberculous granulation tissue round it. ($\times {}^{2}/_{3}$)

In this paper I report observations on the effects of isoniazid on tuberculous lesions in the kidneys of patients treated with isoniazid alone before nephrectomy. These effects, I believe, not only explain the paradoxical clinical findings but also help to show what part isoniazid can be expected to play in the treatment of tuberculosis in general.

Material

Kidneys were obtained from nine patients under treatment with isoniazid alone as part of the M.R.C. trial of isoniazid in genito-urinary tuberculosis at Robroyston Hospital, Glasgow. In seven of the cases nephrectomy was indicated, as in routine genito-urinary practice, by the extent of the tuberculous lesions in kidney and bladder: the period of isoniazid treatment before operation was less than 1 month in four cases, 6 weeks in two, and 3 months in one. In one case nephrectomy was necessitated by deterioration of the patient's condition and by extension of originally minor tuberculous lesions, as shown by pyelography, after 3 months' treatment with isoniazid; and in the ninth case the patient died from uræmia after 3 months' treatment with isoniazid. Three of the patients had received previous treatment, mostly with streptomycin plus P.A.S. The relevant details of the nine cases are given in the appendix.

Suitable control material was already available from examination of specimens in the previous streptomycin trial (Dick 1953), and the lesions were also compared with those after streptomycin alone and after streptomycin plus P.A.S. The control series, now totalling forty specimens from patients who had received, at the time of nephrectomy, no specific drug therapy, showed numerous examples of every variety of tuberculous lesion at all stages, in the naturally occurring state.

Macroscopic Lesions

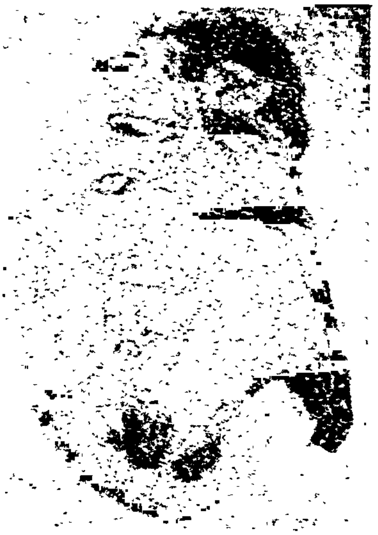

Fig. 3 (case 3)—After 23 days' treatment with isoniazzid, kidney with ulcerocavernous lesion forming "cyst" at upper pole, showing intense congestion round tuberculous lesion, fairly sharply demarcated from rest of organ. ($\times {}^{2}/_{3}$)

Specimens from patients who had been treated with isoniazid, like specimens from untreated patients (figs. 1 and 2), showed all degrees of tuberculous lesions ranging from very small ulcers at the tip of one or more calyces, through fairly large ulcerocavernous lesions involving a small or a large part of a zone or a pole (the commonest stage), to extensive lesions involving all the calyces and leaving a thin rind of kidney tissue.

To the naked eye the lesions in the specimens after treatment with isoniazid showed a degree of congestion most unusual in tuberculous lesions. In addition, frank hæmorrhages were found either in the cavity (fig. 3), in the cortex and under the capsule (fig. 4), or under the mucosa of the calyx or pelvis (see especially the upper pole in fig. 5). Some congestion in the calyx and pelvic mucosa was found in several of the untreated specimens owing to secondary pyogenic infection, but

TABLE I—RESULTS OF DIAGNOSTIC TESTS BEFORE TREATMENT

—	Histology positive	Chronic endometritis	Histology negative
Guineapig test positive	26	3	8
Guineapig test negative	4 (2 not done)	-	

Culture was positive in 6 cases

A clinical trial of isoniazid in female genital tuberculosis was started in Newcastle upon Tyne, 43 patients with tuberculous endometritis and 3 with tuberculous cervicitis being chosen In 17 of these patients adnexal masses were palpable on pelvic examination, in none was there any gross disturbance of general health

DIAGNOSIS

The diagnosis was confirmed in all the cases by curettage in the premenstrual phase immediately before treatment The tissue obtained was examined histologically, by guineapig test, and by direct culture on Lowenstein Jensen (L J) medium The results are shown in table I

The guineapig test was positive in 37 patients, 29 patients showed typical histological evidence of the lesion in the endometrium, and 3 others showed a chronic cellular reaction, suggestive but not typical of tuberculosis Of the 14 patients in whom histological evidence of the lesion was lacking, a microscopical diagnosis of typical endometritis had already been made in 5 at a previous examination In the remainder further sections were cut from the paraffin blocks, and in this way definite microscopical evidence of tuberculous endometritis was found in another 3 patients Histological evidence of the lesion was seen therefore in 37 patients altogether

A direct culture of *Mycobacterium tuberculosis* was obtained from the endometrium in 6 cases In all of these the biological test and histological diagnosis were also positive, suggesting that a direct culture is obtained only in the presence of heavy infection of the endometrium

SENSITIVITY OF TUBERCLE BACILLI TO ISONIAZID AND STREPTOMYCIN

In 20 of the cases in which the biological test was positive the spleen of the guineapig was cultured on L-J medium In all the primary cultures the growth was luxuriant and characteristic of the human type of *Myco tuberculosis* Tests for isoniazid and streptomycin sensitivity were carried out The method of testing for isoniazid sensitivity used in the M R C investigation (Medical Research Council 1952) was followed Isoniazid was incorporated into L-J medium to give concentrations of 0, 0 2, 1, 5, 10, and 50 µg per ml The cultures were compared after two weeks and four weeks with a culture of H37RV inoculated on a similar series of L J slopes, and in all the cases the growth was inhibited at a concentration of 0 2 µg per ml, whereas the controls showed a confluent growth Cultures from only 4 of the 11 patients selected for combined therapy with isoniazid and streptomycin were available for sensitivity tests with streptomycin, and all of them showed inhibition of growth in Dubos medium at a concentration of 0 125 µg per ml The standard strain H37RV was inhibited at a concentration of streptomycin of 0 25 µg per ml

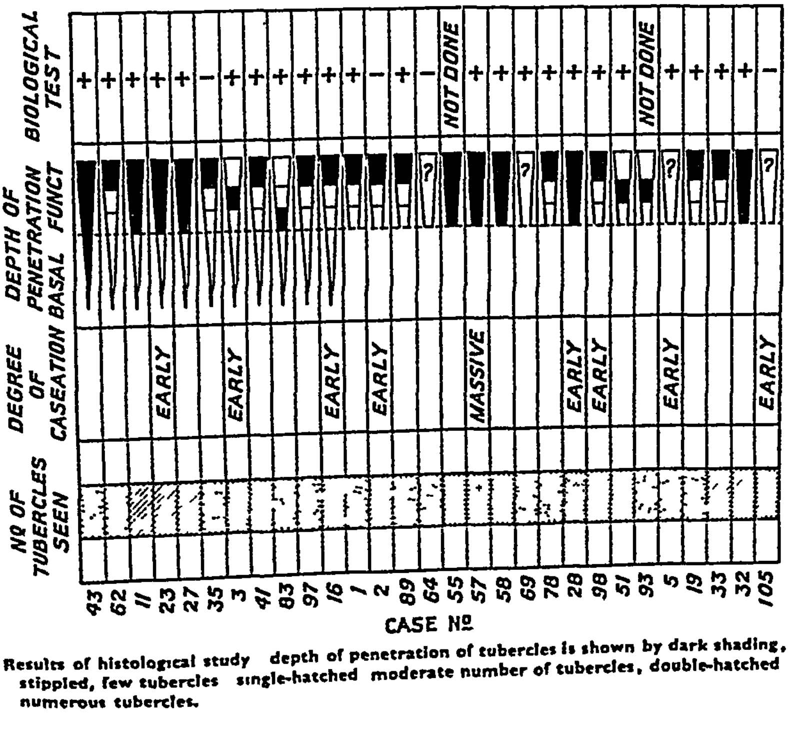
HISTOLOGICAL STUDY

Because it was suspected that the heaviness of the infection, the presence of caseation in the lesion, and the depth to which infection penetrates the endometrium may influence the response of female genital tuberculosis to treatment with antibiotics, a further detailed histological study was made of those 29 sections in which microscopical evidence of tuberculous endometritis had been immediately apparent In this study the degree in which these three factors were present was assessed in each case

The heaviness of infection was roughly estimated by counting the number of tubercles seen during a complete search of each section These were classified as few, moderate in number, or numerous and confluent The amount of caseation present was classified either as nil, early, moderate, or massive The depth to which the lesion penetrated the tissue was also assessed, particular note being made of the presence or absence of tubercles *in the basal layers of the endometrium* In several cases the basal endometrium was difficult to identify with certainty, and, except in those sections in which a portion of myometrium had been included in the field, or in which a vertical section had been cut through the tissues, showing the lumina of the endometrial glands at all levels, it was impossible to distinguish basal endometrium from non-functioning superficial endometrium

The results of this histological study are shown in the accompanying figure In 11 cases basal endometrium was identified, in only 1 case was there evidence of tuberculosis at this depth, and then only one tubercle was seen In the remaining 10 cases the lesion was confined to the functional layer of the endometrium which is shed with each menstruation In 13 cases only a few tubercles (from one to six) were found in the endometrium, in 10 cases a moderate number were present, and 6 cases showed *a numerous confluent distribution* of tubercles throughout the section Caseation was absent in 20 cases, and in the remaining 9 cases only early caseation was present, except 1 case in which massive caseation was present There seemed to be no relation between the number of tubercles present and the degree of caseation, suggesting that all these lesions were of recent contemporary origin

In the 3 cases with tuberculous cervicitis the diagnosis was made on histological



Results of histological study depth of penetration of tubercles is shown by dark shading, stippled, few tubercles single-hatched moderate number of tubercles, double-hatched numerous tubercles.

The reason for this reappearance of tubercles in the endometrium is obscure There seem to be three possible explanations

(1) An active tuberculous focus persists in a fallopian tube in spite of antibiotic therapy, and this is responsible for reinfection of the temporarily cured endometrium

(2) Tubercle bacilli persist in an inhibited state in the endometrium, where after a time they become reactivated and give rise once again to histological response in the tissues in this event one has to suppose that the bacilli remain in the basal layer of the endometrium, for they would otherwise be shed during menstruation in the intervening period

(3) The endometrial lesion is periodically renewed by an intermittent tuberculous bacillæmia which arises from an active tuberculous focus in a remote situation in the body (Haines 1951)

(1) As regards reinfection from a persisting tuberculous focus in the fallopian tube, it is clearly impracticable to obtain a biopsy from the fallopian tube both before and after treatment with antibiotic agents Apart from clinical appraisal of the alteration in size of adnexal masses, and changes in the clinical condition of the patient while under treatment, it is seldom possible to assess the effect of antibiotic therapy on a lesion in this situation

Hence very little is known about the response of tuberculous salpingitis to antibiotics O'Driscoll (1951) has reported a patient who received 135 g of streptomycin and underwent surgery towards the end of the course, a persisting active tuberculous lesion was found in a fallopian tube

Florey (1952) has emphasised the relevance of the cytological pattern of the tubercle to its response to treatment with antibiotics He has pointed out that chemotherapeutic agents introduced by the systemic route must not only be transported to the site of the disease but must also be able to penetrate the avascular caseous area surrounding the lesion, the wall of the giant cell, and the waxy outer envelope of the tubercle bacillus P A S has no intracellular action, while streptomycin has only a limited action within the cell The activity of isoniazid, owing to the smallness of its molecule, is as great inside as outside the cell The unique absence of caseation from the lesion in tuberculous endometritis, in which respect it differs from tuberculosis in every other part of the body, and the invariable presence of caseation in tuberculous salpingitis, lead one to expect the lesion in the endometrium to respond more readily to antibiotic therapy than the lesion in the fallopian tube Reinfection of a temporarily cured endometrium from a persisting focus in the tube therefore seems to be likely

(2) As regards the persistence of tubercle bacilli in the basal endometrium, Ryden (1950) reports that tubercles can be found in the basal endometrium in all cases in which a careful search has been made This is contrary to the classical description of the histology of tuberculous endometritis by Schroder (1921), in which the lesion was shown characteristically to be confined to the superficial layers, a concept confirmed later by many pathologists including Delarue and Bergerot-Blondel (1949) and also by the present findings (see figure) It therefore seems unlikely that infection can persist in the basal endometrium unless we postulate that tubercle bacilli may ordinarily be present in the basal layer without giving rise to any histological response in this situation

(3) As regards periodical renewal of the endometrial lesion by intermittent tuberculous bacillæmia, in a survey of a large series of cases with pelvic tuberculosis to which reference was made by one of us at the Congress of Obstetrics and Gynæcology at Leeds (Smith 1952) we have shown that tuberculous infection is disseminated to the genital tract early in the postprimary phase of the general infection of the body by the tubercle bacillus These findings are inconsistent with the concept of periodical renewal of the lesion in the endometrium by intermittent bacillæmia throughout life, derived from an active tuberculous focus elsewhere in the body

We want to emphasise that this is only a preliminary report on the initial response of tuberculous endometritis and tuberculous cervicitis to treatment with isoniazid We propose to repeat all these investigations on these patients in a year, by which time the comparative effectiveness of isoniazid used alone with that of isoniazid used in combination with other antibiotics may have become apparent The significance of the cytological factors assessed histologically in the present series may also be apparent by that time We do not claim that the response which followed treatment with these drugs is in any way permanent, but that it is nevertheless of therapeutic value is proved by the fact that one of these patients has already become pregnant

SUMMARY

The effect of isoniazid on pelvic tuberculosis has been assessed in 43 patients with tuberculous endometritis and 3 with tuberculous cervicitis

The patients were divided into two groups, of which one received isoniazid only and the other isoniazid, streptomycin, and P A S

All the cases were confirmed by histological, biologica or cultural examination All the cultures that were obtained were of the human strain of tubercle bacillus

Only 2 patients with tuberculous endometritis and 1 with tuberculous cervicitis did not respond to treatment, 40 showed no evidence of infection after treatment, and 1 became pregnant

Since endometrial lesions often reappear twelve months or more after treatment with streptomycin, these *apparent cures cannot be regarded as permanent* Relapse after treatment may be due to persistence of the lesion in the fallopian tubes, where caseation, insulating the bacillus from the action of the antibiotic, is usually present Ryden's (1950) findings of persistent tubercles in the basal endometrium have not been confirmed in the present study

We have also shown that tuberculous dissemination occurs during the early postprimary phase of gener infection of the body by the tubercle bacillus, a vie inconsistent with Haines's (1951) concept of periodic renewal of the endometrial lesion by bacillæmia fro remote foci

We wish to thank Dr B E Tomlinson, who supplied th histological reports for this study Our thanks are al extended to Messrs Roche Products, who provided th 'Rimifon' (isonicotinyl hydrazide) used in this clinic trial

The volume of basic knowledge which must be mastere by the medical students of today is far greater than eve before And yet we are now urged to teach students l about the science of medicine and more about the practica aspects of home care and office practice Why, may I ask should the undergraduate curriculum be any different for a general practitioner than for a neurosurgeon ? *Do they no both have to know a maximum of medical science* ? — W BARRY WOOD, jun, M D *J Lab clin Med* 1953, 41, parenchyma. Another feature, seen in the medulla of these specimens, was the numerous irregular or rounded areas of eosinophilic material between the tubules, infiltrated and surrounded by numerous congested capillaries (fig. 13). From intermediate stages throughout these specimens it was concluded that this appearance sometimes represented a late stage in the disappearance of a tuberculous follicle which was being absorbed, although similar appearances were found in non-tuberculous healing lesions.

AFTER THREE MONTHS' TREATMENT WITH ISONIAZID AND NO PREVIOUS CHEMOTHERAPY (CASES 5 AND 6)

In the specimens from these cases there was a sharp distinction in appearances between lesions in the cavities, calyx, and pelvis, and in the isolated follicles in the renal parenchyma. The recent open lesions showed a diminution of the good effect seen in the cases treated for a month or less, though there were still modifications from the appearances in untreated cases. The zone of reaction in the cavity wall (fig. 14) was broader than in figs. 6 and 7, though still not nearly so broad as in an untreated cavity. There was still minute vacuolation of the caseation in parts, as if some absorption was taking place, but in other parts there appeared to be direct extension of the caseation into the surrounding tissues. The vascularity was still prominent and, if anything, increased. The greatest change, however, was in the increased cellular reaction: epithelioid cells were prominent, with slight fibrosis between them; a few giant cells had developed at the caseating margin; and there was a slight increase in lymphocytic infiltration.

In older parts of cavity walls with dense fibrosis (fig. 15) caseation appeared to spread into the fibrosis, which softened before it; and, although there was no clear zone of epithelioid cells, there were considerable round-cell infiltration and vascularity beyond the advancing caseation.

Towards the calyx, at the neck of the cavity, a vascular granulation tissue showed signs of reactivating tuberculosis: the superficial layer (fig. 16) showed epithelioid cells lining the lumen, more active in appearance than the vacuolated caseation in fig. 11; and elsewhere active epithelioid follicles from deeper in the submucosa (fig. 17) were ulcerating to the surface. In addition to the renewed activity of tuberculous lesions, the vascularity and lack of fibrosis were prominent features in this site.

LEGENDS TO ILLUSTRATIONS

Fig. 14 (case 5)—Renewed acute caseation in edge of cavity. Part of the picture shows epithelioid cells with vacuolation of caseation between them, and other parts show no barrier at all, the caseation extending directly into vascular granulation tissue. (× 100.)

Fig. 15 (case 5)—Renewed caseation in chronic cavity. The caseation extends directly, with few epithelioid cells, into fibrous wall. (× 100.)

Fig. 16 (case 6)—Vascular granulation tissue at neck of cavity with margin of poorly formed epithelioid cells. (× 100.)

Fig. 17 (case 6)—Epithelioid follicle, in vascular granulation tissue wall, rupturing to surface. (× 100.)

Fig. 18 (case 6)—An old follicle, the fibrosis of which has become converted to almost homogeneous eosinophilic material, with hæmorrhage into it and numerous congested capillaries surrounding it to absorb it. (× 100.)

Fig. 19 (case 5)—An old follicle, with giant cell round concentric laminated body: there are loose cells round but no dense fibrosis. (× 100.)

Fig. 20 (case 6)—A giant cell and epithelioid follicle showing no evidence of fibrosis. (× 100.)

Fig. 21 (case 6)—Aggregation of fibrosed epithelioid follicles with prominent tubules in and round them. Follicle nearest surface shows loss of fibrosis with recent caseation centrally and no clear demarcation from kidney parenchyma—a recently spreading lesion. (× 50.)

Thus, in these open-cavity lesions the early beneficial effects of isoniazid had been partially lost after 3 months' treatment. As regards the isolated tuberculous lesions (small and large) scattered throughout the renal parenchyma, the changes were much greater after 3 months' treatment than after less than 1 month's treatment, and were far different from those found in controls.

In two-thirds of the untreated specimens small and acutely caseating follicles were present, causing active destruction of the kidney tissues. All of them showed epithelioid follicles with or without central caseation and with either early or well-marked surrounding fibrosis, which had in some cases penetrated diffusely into the surrounding parenchyma.

In specimens after treatment with isoniazid, however, small caseating follicles seemed inactive, as if all the elements so characteristic of tuberculous lesions were melting into a homogeneous fibrinous matrix (fig. 18), which was then becoming vascularised by numerous congested capillaries, and there were often small central hæmorrhages, ultimately becoming absorbed, the later stages of small recent lesions of this kind having been found earlier (fig. 13). Even old fibrosed lesions with concentric laminated bodies showed a loosening of the fibrosis (fig. 19). Individual epithelioid follicles, too, showed œdema and loss of fibrous tissue (fig. 20) both throughout the lesion and round it. If there had been old fibrosis round it, this was now much less compact, and the collagen was disappearing. This loss of compact fibrosis round old epithelioid lesions even permitted breaking out of fresh caseation in larger lesions (fig. 21). Another feature noticed in these lesions was the prominence and apparent rejuvenation of tubules round the lesions (fig. 21).

AFTER ISONIAZID TREATMENT FOLLOWING PREVIOUS CHEMOTHERAPY (CASES 7–9)

The effects on the histological lesions in renal tuberculosis of streptomycin alone and of streptomycin and P.A.S. have been described already (Dick 1953).

To summarise, a 3-month course of streptomycin alone checked acute caseation, encouraged considerable fibrosis along the edges of chronic caseating cavities, and caused a dense fibrous reaction round all the isolated lesions scattered throughout the renal parenchyma. When streptomycin-resistant strains of the tubercle bacillus became predominant, the beneficial effect of the fibrosis was nullified by renewed caseation, especially in the mucosa of calyx and pelvis. Streptomycin and P.A.S. caused an even greater fibrosis round all tuberculous lesions, and no lesions still actively caseating were found after a 3-month course of these drugs combined.

In the present series cases 7 and 8 had received about a month's treatment with streptomycin and P.A.S. followed by 6 weeks' isoniazid treatment before nephrectomy, yet their lesions were completely different histologically. In case 7, a boy aged 7 years, the tuberculous lesions were all becoming inactive. There were three small cavities at the tip of one calyx, all showing fresh growth of epithelium on the surface (fig. 22), with a few small absorbing follicles scattered under it. Scattered caseous lesions in the parenchyma were still well fibrosed. The numerous epithelioid follicles were loose, vacuolated, infiltrated with lymphocytes (figs. 23 and 24), and gave little evidence of tuberculous activity. The isoniazid appeared to be controlling the infection. Case 8 was of peculiar interest because there were two ureters, one draining the upper pole and the other the mid-zone and lower pole, but both drainage areas showed extensive tuberculous lesions (fig. 5). In these lesions there were extensive areas of modified caseation, as in fig. 14, with no evidence of fibrosis in some cavities while others showed patchy fibrosis. Thus the isoniazid was not controlling the infection in the open lesions. That it was having some effect in the isolated lesions was shown by the appearance of some epithelioid follicles (fig. 25) thromboplastin suspension. The mixture is placed in a water-bath at 37°C for 5 minutes, 0.2 ml. 0.33% calcium chloride solution is added, and the time required for clotting is measured.

A correlation graph is prepared from dilutions of normal plasma. The clotting-time of 1:10 dilution of normal plasma in barbitone buffer is regarded as equivalent to 100% prothrombin activity. Higher dilutions of the normal plasma are made with a barbitone buffer containing 30 mg. potassium oxalate in 100 ml. solution.

The accompanying figure shows the distribution of results by Quick's and Owren's methods of determining prothrombin activity in 80 cases where tromexan was given in varying amounts. Statistical analysis of the figures does not reveal any significant difference between the two sets of observations. In the therapeutic range of activity—i.e., 10–25% of prothrombin activity—there were 37 results by one method and 39 by the other. The only pronounced difference between two groups of results was at 15–20% and 20–25% of prothrombin activity. In our opinion this is immaterial. The experiment also provides evidence that factor V is not affected by the administration of tromexan.

In view of our experimental results, we believe that it is unnecessary to add a sample of factor V to every routine prothrombin test, and that Owren's one-stage prothrombin test has no practical advantage over that of Quick's. Owren's method may have certain definite advantages from the research point of view.

A typical series of results is shown in table I. The clotting-time of normal plasma by the modified Quick method using thromboplastin (Geigy) is 15.6–18.2 seconds. The addition of factor V does not shorten the clotting-time significantly; when factor VII is added there is a distinct shortening of the clotting-time which tends to approach the optimum clotting-time of 12–15 seconds (Biggs et al. 1953). Further work on this aspect of blood coagulation will be described in a later communication.

TABLE I—CLOTTING-TIME (SEC.) OF NORMAL PLASMAS WITHOUT AND WITH THE ADDITION OF FACTOR V OR FACTOR VII

Normal plasma	Normal plasma with factor V added	Normal plasma with factor VII added

15.6		
16.4	15.8	15.0
16.0		
17.6	16.4	14.4

PROTHROMBIN TIME OF TROMEXAN-TREATED PLASMA WITH ADDED FACTOR V AND FACTOR VII

Specimens of plasma were obtained from patients receiving tromexan. Clotting-times were estimated by the method of Quick, modified as above and also by the addition of one other reagent. Thus 0.2 ml. factor-VII preparation or 0.2 ml. factor-V preparation, or in the control 0.2 ml. of normal saline, was added to 0.2 ml. plasma, 0.2 ml. thromboplastin suspension, and 0.2 ml. calcium chloride solution, and the time taken for the mixture to clot determined in a water-bath at 37°C.

The results of this experiment are shown in table II. The addition of plasma containing factor V did not make any significant difference to the clotting-times. Addition of serum samples containing factor VII shortened the clotting-times in every case, and statistical analyses of the two groups show that the result is highly significant.

TABLE II—EFFECT OF FACTOR VII ON THE CLOTTING-TIME (SEC.) OF TROMEXAN-TREATED PLASMA

T.P. = Tromexan-treated plasma. F.V. = Factor V.
T. = Thromboplastin. F.VII = Factor VII. Ca = Calcium.

Several of the clotting-times when factor VII is added are in the region of 14 seconds, which is shorter than the clotting-time, measured by the modified Quick method, *of normal plasma using thromboplastin (Geigy)* (table II).

It is evident therefore that the addition of serum containing factor VII will greatly shorten the clotting-times of tromexan-treated plasma. The only adequate explanation for our findings is that the prothrombin of tromexan-treated plasma is still present but its conversion to thrombin is delayed because of a deficiency of factor VII. Owen and Bollman (1948) and Koller et al. (1951) describe similar findings for dicoumarol-treated plasma.

DISCUSSION

Until 1943 it was generally believed that the low clotting power of blood in dicoumarol poisoning and in vitamin-K deficiency was due to a fall in prothrombin content. It was believed that even in the presence of an abundant supply of thromboplastin and calcium ions thrombin was formed in insufficient amounts to ensure proper conversion of fibrinogen to fibrin. The work of Quick, Owren, and others suggests that what is estimated as "prothrombin" may in fact be a complex of two or more substances.

We have prepared by Owren's method plasma and serum samples which contain factor V and factor VII, the latter being free from prothrombin. When the factor-V preparation is added to tromexan-treated plasma the clotting-time is not shortened; this finding agrees with those from experiments with dicoumarol-treated plasma and suggests that factor V is little, if at all, affected by tromexan.

We have also reported evidence that factor VII, which is present in plasma and serum (Koller et al. 1951, Biggs and Macfarlane 1953a and b), accelerates the clotting of tromexan-treated plasma and that this defect results from the administration of tromexan. This evidence as to the mode of action of tromexan agrees with that of Owren (1950) and Owen et al. (1951), who studied dicoumarol-treated plasma. Owen et al. state:

The rate with which prothrombin converts to thrombin would seem to be a function of these accessory factors

Hæmophilic plasma dil 1 100 (ml)			0 1	
Clotting time (min)	12	14	26	360
Patient's blood (ml)	1 0	1 0	1 0	1 0
Normal plasma (ml)	0 1			
Normal plasma dil 1 10 (ml)		0 1		
Normal plasma dil 1 100 (ml)			0 1	
Clotting time (min)	13	17	24	360

(2) The plasma of a hæmophiliac in the same dilutions caused the same reduction of the coagulation time in our patient as normal plasma did

(3) Intravenous injection of fraction I of Cohn (Cohn et al 1944) (carrier of the antihæmophilic factor=A H F) did not reduce the coagulation-time in our patient, whereas transfusion of normal plasma did so—e g , from 5 hours to 22 minutes after an hour

(4) In vitro the A H F did not reduce the coagulation time in our patient

(5) The fraction active in hæmophilia (Bendien and van Creveld 1937) which can be precipitated by adding 1/10 *N* acetic acid to tenfold diluted fresh plasma till the pH is 5 4 had no influence on the prolonged coagulation time in our patient However, after precipitation of this fraction, the supernatant fluid did promote coagulation

The boy did not have hypoprothrombinæmia, because .

(1) His prothrombin time (Quick) was normal This fact also indicated that a deficiency of one of the factors active in the conversion of prothrombin into thrombin in the presence of thromboplastin and calcium was highly improbable (see below)

(2) The prothrombin content, determined by the two stage method, was also normal

The boy had not got parahæmophilia, because the prolonged prothrombin-time of normal stored plasma, which does not contain plasma Ac-globulin [=proaccelerin (Owren 1952)=labile factor (Quick 1943, 1947)=factor V (Owren 1947)], could be reduced to normal by the addition of small quantities of our patient's fresh plasma Moreover the quantitative determination of plasma Ac-globulin in the plasma of our patient by the method of Ware and Seegers (1948) gave a normal value

We still had to examine the concentration of proconvertin (Owren 1951) in the plasma of our patient In this connection we had to keep in mind that some cases of hæmorrhagic diathesis have been described where a deficiency of an unknown coagulation factor was found Clinically this disease may resemble parahæmophilia and hæmophilia Such cases have been described by Koller et al (1951), Alexander et al (1948), Alexander (1952), Owren (1951, 1952), and Beaumont and Bernard (1952) In those cases the plasma is deficient in a factor which differs from plasma Ac globulin but which is also necessary for the normal conversion of prothrombin into thrombin This factor is present in a rather inactive form in plasma and in an active form in serum Alexander et al have named the rather inactive form S P C A precursor, and the active form S P C A , Owren calls them respectively proconvertin and convertin , and Koller calls the active form factor VII

Biggs et al (1952) assume that the factor lacking in Christmas disease is probably identical with Koller's factor VII but differs from it in other ways Both factors are present in the serum in a stable form, and both can be adsorbed by asbestos (Seitz filter), barium sulphate, and aluminium hydroxide The difference between them is that the Christmas factor is necessary for the formation of thromboplastin, whereas factor VII is required for the conversion of prothrombin into thrombin Hence both factors should be active at different stages of coagulation

The determination of proconvertin in the plasma of our patient according to Owren's method gave a value which was 60% of normal This proved with certainty that the hæmorrhagic diathesis of our patient was not caused by a *hypoproconvertinæmia* (*Alexander* et al found only 3%, and the coagulation-time and prothrombin consumption at coagulation were only slightly abnormal)

Other arguments against the diagnosis of hypoproconvertinæmia were

(1) The addition of a very small quantity of thromboplastin to our patient's blood greatly reduced the coagulation time (as in hæmophilia) This does not happen in hypoproconvertinæmia and in parahæmophilia

(2) The prothrombin time of our patient, determined by the one stage method, was normal

So we must conclude, as did Aggeler et al (1952), Schulman and Smith (1952), and Biggs et al (1952), that there was a *deficiency of a thromboplastin component* which differs from the thromboplastin component absent in hæmophilia (A H F) Further, by the thromboplastin generation method recommended by Biggs et al we could demonstrate in our case an inability to form *blood-thromboplastin*

We have previously reported (van Creveld and Paulssen 1952) the isolation from normal thrombocytes of factor 3, which is necessary for the formation of thromboplastin in the blood At that time the Christmas factor was still unknown, and we concluded from our investigation that factor 3 and A H F cooperated to form thromboplastin In the light of the present findings it may be concluded that A H F , Christmas factor, and factor 3 together form thromboplastin

Transfusions of blood and plasma have a favourable effect on the clotting-time in Christmas disease In our patient the effect of such a transfusion lasted longer than in hæmophilia Therefore it is very likely that after *transfusion the Christmas factor disappears* less quickly from the blood than does the antihæmophilic factor in hæmophilia

SUMMARY

A case is described which clinically resembled hæmophilia, except that the antihæmophilic factor was present in the plasma, and another coagulation factor was lacking

The disease belongs to the group of cases included under the name of Christmas disease

In the differential diagnosis emphasis is laid on the difference from the hæmorrhagic diathesis due to a deficiency of a prothrombin conversion factor, called proconvertin (Owren) and S P C A precursor (Alexander)

sistant strains could be diminished very considerably y combining isoniazid therapy with streptomycin herapy. It remains to be seen how this combination ill affect the histological changes caused by each drug eparately; and, if the results are satisfactory, it will e some years before suitable material will be available or examination. It does appear, from the cases in this eries previously treated with streptomycin, that the eneficial effects of isoniazid will take full effect. It hould be pointed out, however, that after treatment vith combinations of drugs the changes in the histological icture may be so altered or even cleared up that a etrospective diagnosis of tuberculosis by biopsy or ecropsy may be almost impossible. Thus, in future it vill be even more essential than before to establish the liagnosis firmly before treatment is begun.

Summary

Changes are described in tuberculous lesions in kidneys from nine patients who had been treated with isoniazid alone: four of the patients had been treated for less than a month, two for about 6 weeks, and three for 3 months. Three of the patients had received previous chemotherapy.

The macroscopic changes were congestion and hæmorrhages in relation to the tuberculous lesions.

The microscopic changes were absorption of recent caseation, vascularisation of all stages of tuberculous lesions, including the dense fibrosis round old lesions, and prevention of fibrosis in and round the lesions.

Open lesions showed the optimal effect after a month's treatment, and regression was taking place after 3 months' treatment; isolated lesions, however, showed more satisfactory effect after the 3-month course.

Some implications of these changes in the tuberculous lesions are discussed as regards the treatment of tuberculosis in general.

With the knowledge of the changes effected in the histological lesions of tuberculosis by the various chemotherapeutic agents, further emphasis is provided, in addition to the clinical findings, that none should be used alone. The various combinations and succession of combinations can be based on rational principles.

I am deeply indebted to Dr. M. A. Foulis, physician-superintendent, Mr. A. Jacobs, consultant urologist, Mr. W. Borthwick, urological surgeon, and Drs. W. G. Wimsett, P. Macpherson, and A. Drimmie, of Robroyston Hospital, for their clinical coöperation: to my colleagues in the department of pathology, Stobhill Hospital, for their helpfulness and criticism: and to Mr. Ian Mackie and Mrs. C. Neilson for their photographic and secretarial assistance respectively.

Appendix

Case 1.—Man, aged 26. Bilateral renal tuberculosis requiring nephrectomy on the worse side. This was done 16 days after the start of isoniazid treatment.

Case 2.—Woman, aged 28. Diffuse disease of the right kidney with involvement of the ureter and bladder. Nephrectomy was done after 18 days' treatment with isoniazid.

Case 3.—Man, aged 46. Unilateral renal tuberculosis with cystitis. After 23 days' isoniazid treatment, nephrectomy was done (fig. 3).

Case 4.—Girl, aged 17. Unilateral renal tuberculosis with involvement of ureter and bladder. After 29 days' isoniazid treatment, nephrectomy and partial ureterectomy were done.

Case 5.—Man, aged 23. Showed cavitation at the lower pole of one kidney and was adjudged suitable for partial nephrectomy. A full 3-month course of isoniazid was given in preparation for this. At operation, however, the ureter was found to be dilated, and nephrectomy was performed.

Case 6.—Woman, aged 22. Presented with a small unilateral lesion and no cystitis. Treatment with isoniazid was pursued for 3 months but the lesion appreciably worsened and cystitis developed, so that nephrectomy was required (fig. 4).

Case 7.—Boy, aged 7. 2 years previously, pain in one loin and colicky pains at times in the line of the ureter on that side. In March, 1952, he had epididymitis, and examination revealed renal tuberculosis. He was treated first with streptomycin 1 g. every third day and P.A.S. for 6 weeks, and then with isoniazid for 6 weeks before nephrectomy.

Case 8.—Man, aged 30. In 1948 he received 90 g. of streptomycin for trochanteric disease: urinary symptoms started in December, 1951. In April, 1952, he received streptomycin 1 g. daily plus P.A.S. for 21 days. In July a full course of isoniazid was started and nephrectomy was done after 6 weeks of the course (fig. 5).

Case 9.—Woman, aged 39, with advanced bilateral renal tuberculosis. During a previous admission (October, 1950–June, 1951), she had received a course of 90 g. of streptomycin followed by another course of streptomycin 90 g. plus P.A.S. In April, 1952, her urine was positive to tubercle bacilli. She died from uræmia after 3 months' treatment with isoniazid. The left kidney was a small sac, the wall 0·5 cm. thick, filled with caseous white debris, and the ureter was kinked at the pelvic brim. The right kidney was large and slightly hydronephrotic, with congested cortex and with tubercles in the papillæ, and the ureter was somewhat dilated.

ISONIAZID IN THE TREATMENT OF FEMALE GENITAL TUBERCULOSIS

TOM BARNS
M.A., B.M. Oxfd, M.R.C.O.G.
RESEARCH FELLOW, DEPARMENT OF OBSTETRICS AND GYNÆCOLOGY, NEWCASTLE GENERAL HOSPITAL, NEWCASTLE UPON TYNE

H. G. M. SMITH
B.Sc. Aberd., M.B. Glasg., Ph.D. Brist., Dip. Bact.
DIRECTOR OF PUBLIC HEALTH LABORATORY, BRADFORD

LINTON M. SNAITH
M.D., M.S. Durh., F.R.C.S., F.R.C.O.G.
SENIOR OBSTETRICIAN AND GYNÆCOLOGIST, NEWCASTLE GENERAL HOSPITAL

In recent years there has been a great increase in the number of cases of female genital tuberculosis diagnosed in the latent stage, largely through the medium of infertility clinics. These patients formerly received no active treatment, but the advent of streptomycin and *p*-aminosalicylic acid (P.A.S.) led to attempts by many workers (Schaupp 1949, Delarue and Bergerot-Blondel 1949, Ryden 1950, Stallworthy 1950, Sutherland 1952) to eradicate the disease completely with these drugs, even to the extent of permitting pregnancy. So far results have been disappointing; even though the preliminary response appeared favourable, there was evident a very strong tendency towards the reappearance of tuberculous follicles in the endometrium even six months or more after apparent cure. Intra-uterine pregnancy in an established case of pelvic tuberculosis has been reported only very rarely (Rabau 1952, Stallworthy 1952).

œsophagus in the region of the tracheal bifurcation In other films of this area mucosal ridges are seen which show a lateral twisting from their normal longitudinal course

COMMENT

The presumed arrangement of the great vessels in this case is shown in fig 2 Obliteration of the anterior loop of the arterial vessel by side-to side digital pressure in the region marked with an X led to disappearance of both femoral pulses, both radial pulses, and the right carotid pulse Fig 3 represents the probable pattern of persistence of arterial vessels in the primitive formation (Congdon 1922)

Our patient has been under observation periodically for the past sixteen years There has been no great change in the cervical aortic knuckle, and his symptoms have never been severe He is regular in attendance at his work and has had no serious illnesses The presence of the large double arterial trunk in the confined space of the thoracic inlet does not seem to have given rise to any ill effects should it do so, a case may be made for enlarging the space by removal of the first rib on the right side

A CASE OF POLYORCHIDISM

P St G Anderson
M B Dubl , F R C S E
SURGICAL REGISTRAR, SWINDON AND DISTRICT GROUP OF HOSPITALS

Polyorchidism is a surgical curiosity, and the number of published cases is small Lowsley and Porras (1951) found 18 authentic cases and added 1 of their own The differential diagnosis is from a spermatocele and from a hydrocele of the cord, and the diagnosis is usually established at operation

Embryology—The testis arises from the medial side of the urogenital ridge, whereas the epididymis and vas deferens are derived from the mesonephric ducts The müllerian duct disappears in the male, except when the upper end may persist as the appendix testis of Morgagni The lower end, by fusion with the opposite side, forms the prostatic utricle As the testis descends, new seminiferous tubules are formed caudally, while the cephalad ones degenerate If the anterior seminiferous tubules persist, an extra testis may develop with a common vas deferens and epididymis

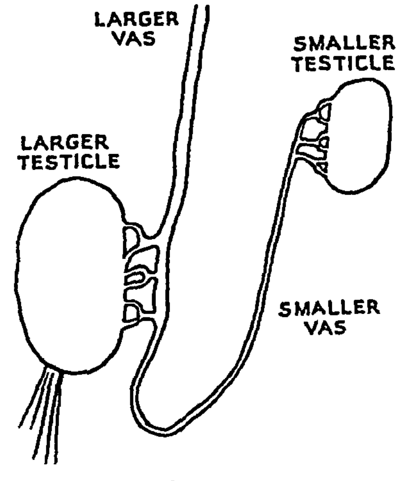

Fig 1—How the two testicles lay in the left side of the scrotum

Case record—A young man, aged 19, was admitted to hospital with a history that seven hours previously he had suddenly developed a painful swelling in the left groin and had vomited once There was a tense tender irreducible swelling in the left groin, and a diagnosis of strangulated left inguinal hernia was made

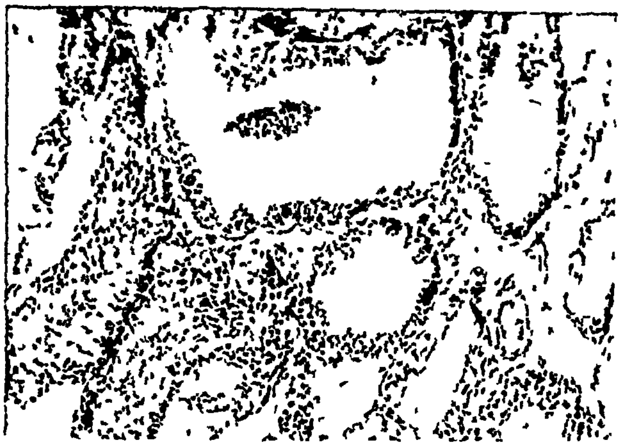

Fig 2—Biopsy specimen of larger testicle (× 85)

The swelling was explored through an inguinal incision After exposure of the cord what was thought to be a hernial sac was incised, clear fluid escaping This proved to be a hydrocele containing two distinct swellings, both of which appeared to be testicles The hernial sac was found just above the hydrocele, it was opened, viable bowel was returned to the abdomen, and the sac was transfixed and excised The vas was traced from the internal ring to the lower testicle, and a smaller vas was found which was traced from it to the smaller and upper testicle (fig 1) A piece of tissue was removed from each for biopsy As each swelling was incised, the typical spongy yellow appearance of testicular tissue was seen While the two left sided testicles were palpated an independent observer was able to palpate a normal testicle in the right side of the scrotum After the biopsy the wound was closed in layers

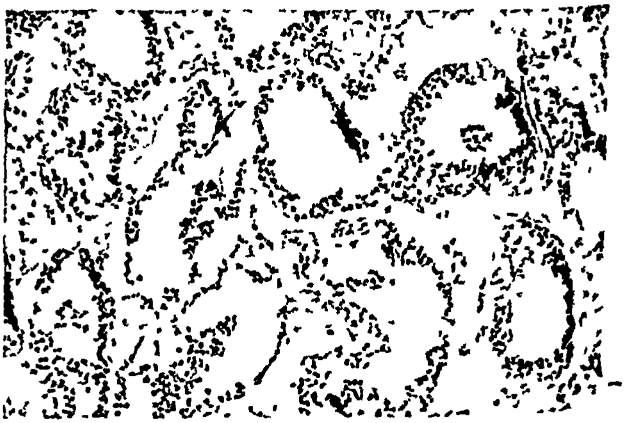

Fig 3—Biopsy specimen of smaller testicle (× 85)

The patient made an uninterrupted recovery, and some weeks later all three testicles were easily palpated the upper one on the left side lying in a high scrotal position

Biopsy Reports—The biopsy specimens were both composed of testicular tissue In neither was there any spermatogenesis, but proliferation of the spermatogonia was well marked (figs 2 and 3)

I wish to thank Mr J E Schofield under whose care the patient was admitted, for permission to publish and Mr R Thexton, H D D , L D S , for the drawing

examination and confirmed by biological test. In 2 of these cases the lesion was a frank fungating growth on the portio vaginalis; in the 3rd case the cervix appeared healthy on inspection, but tuberculous endocervicitis was found on biopsy. Massive caseation was present in one of these lesions.

TREATMENT

All the patients were treated with isoniazid (' Rimifon,' Roche) 150 mg. daily for sixteen weeks. 11 patients were also given streptomycin 1 g. daily and P.A.S. 15 g. daily in addition to isoniazid during the last eight weeks of the course. These drugs were added because, during the conduct of this trial, the reports of Joiner et al. (1952) and the Medical Research Council (1952) showed that the development of isoniazid resistance could be postponed or averted by using these drugs together.

TABLE II—RESPONSE TO THERAPY

—	Histology positive	Chronic endometritis	Histology negative
Guineapig test positive	..	..	1
Guineapig test negative	1	..	40

Culture was negative in all the cases. One patient was pregnant.

The patients were seen at intervals throughout treatment. At each visit the central nervous system was examined completely, the blood-pressure was estimated, the patients were weighed, the hæmoglobin was estimated, and total and differential white-cell counts were made. No side-effects from isoniazid were noted in any of these patients, and none of the aforementioned tests showed any deviation from normal. Only 4 patients gained more than 4 lb in weight, and none developed abnormal appetite. A patient who received streptomycin and P.A.S. in addition to isoniazid developed a rash on her chest and complained of feeling weak; streptomycin therapy was therefore discontinued after 30 g. had been given.

RESPONSE TO THERAPY

Response to treatment was assessed in 42 cases by repeating full-scale curettage in the premenstrual phase within six weeks of finishing treatment. The results of this investigation are shown in table II.

2 patients with tuberculous endometritis did not respond to treatment. In 1 of them histological evidence of the lesion persisted, although the biological test and direct culture, both of which had been positive before treatment, had now become normal. This case is of interest because it was the only one in which massive caseation had been seen in the endometrium on histological study. In the second case which failed to respond the biological test remained positive, although histological evidence of the lesion had disappeared. Tests for isoniazid sensitivity were made on the culture obtained from the spleen of the guineapig in this case; and the organism was found to be still sensitive to isoniazid.

Of the 3 patients with tuberculous cervicitis 1 did not respond; this also was the only case in which massive caseation had been present in the cervical lesion before treatment.

40 cases of tuberculous endometritis and 2 of tuberculous cervicitis were apparently cured, no evidence of tuberculosis being found either on histological examination, biological examination, or by direct culture. No significant alteration in the size of the pelvic masses was noted in any of these cases.

1 other patient was not curetted, because she became pregnant while under treatment. Only 2 other cases of pregnancy in patients with tuberculous endometritis have been published (Stallworthy 1952, Rabau 1952). In Rabau's patient the original diagnosis had rested upon a positive biological test, although histological evidence of tuberculosis was absent; the patient aborted in the third month of pregnancy. In the present case, the diagnosis was also made on the result of one biological test, no evidence of the lesion having been found on histological examination, although curettage was repeated twice during the three months preceding treatment. The patient was treated with isoniazid, streptomycin, and P.A.S. and became pregnant while receiving these drugs; she is now six months pregnant, and the Hogben test is positive. Her treatment is being maintained throughout pregnancy to prevent a relapse in her condition.

DISCUSSION

We are sceptical about the permanence of these apparent cures. This scepticism is founded upon the disappointing end-results which have followed the treatment of tuberculous endometritis with streptomycin and P.A.S. at the Newcastle General Hospital during the past three years. In most cases treated in this way, although all trace of the lesion disappears shortly after treatment, relapse occurs after an interval of twelve months or so. In table III are shown the end-results of antibiotic therapy in all the cases treated in this way at Newcastle during the past three years. The dosage used was admittedly small in comparison with that recently advocated by Sutherland (1952); but the tendency for the condition to relapse after treatment is demonstrated.

TABLE III—END-RESULTS AFTER STREPTOMYCIN THERAPY

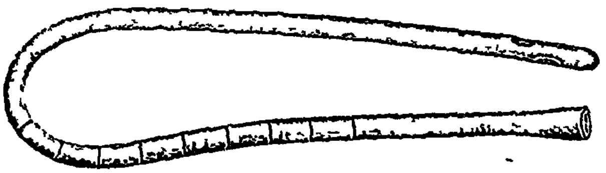
THE USE OF A GRADUATED CATHETER IN RETROPUBIC PROSTATECTOMY

DURING retropubic prostatectomy the urethral catheter is inserted before the prostatic capsule is closed This enables the surgeon to place the catheter in the bladder under direct vision However, at the end of the operation, when the surgeon proceeds to fix the catheter with strapping or by some other means, it may have altered position

I believe a simple method of overcoming this difficulty is to use a graduated catheter This is a Harris catheter 14 in long Starting at 8 in from the tip, it is graduated in half-inch and inch divisions The marks indicating inches form a complete ring round the catheter, the half-inches being denoted by half-rings



When the catheter is inserted during the operation, the body of the penis is stretched fully over it, and the mark opposite the external urinary meatus is noted After the operation the catheter is fixed at this reading This has been found at St Peter's Hospital to be on an average about 11 in

An additional advantage of a graduated catheter is seen postoperatively The nurses are informed of the correct reading If the catheter is not draining satisfactorily, a glance at the graduations will show whether it is in the correct position in the bladder

The catheter illustrated is made by the Genito-Urinary Company, 28A, Devonshire Street, London, W 1

"There is a sense in which the present is an age of which a characteristic is its failure to understand the status of its own abstractions, and this perhaps is the inevitable fruit of the divorce of natural science from metaphysics, to have achieved which was the empty triumph of the nineteenth century Thus those who are outright opponents of the notion that there must be an immaterial element in the human person have, for the most part, no language in common with those who think otherwise For the problem involved is essentially metaphysical and for the materialist metaphysics are sour grapes —Dr F M R WALSHE, F R S, *Brain*, 1953, 76, 1

Medical Societies

ROYAL SOCIETY OF MEDICINE

Psychiatry in General Practice

THE psychiatric section of the society met on April 1 under the chairmanship of Dr W S MACLAY, preside of the section, to discuss Psychiatry in General Practic

Dr JOHN FRY gave an account of his experience the psychiatric problems in 1951 and 1952 in a suburb middle class practice of about 4500 patients In 195 out of 14,602 attendances 1379 were for psychiatr disorders, in 1952, of 14,821 attendances 1422 we psychiatric Patients receiving treatment for psychiatr illness out of the total population of his practice were in 1951, 502 out of 4406, and in 1952, 570 out of 470 From both these angles, psychiatric cases figured about 10% of his work, but the average attendances a psychiatric patient were 5 per annum, compared wi the non-psychiatric patient's average of 3

He had found that psychiatric illness was the third mo prevalent form of illness, exceeded only by respirator and gastro-intestinal diseases

Women psychiatric patients outnumbered men b 5 to 2, whereas in other types of illness the sexes we nearly equally represented As regards age, th attendance rates for psychiatric illness rose sharply i the 40–60 age group, this was almost entirely due t psychiatric illness among women in the involutiona period

The ways in which the psychiatric patient presented himself varied There was the tonic seeker, for whom the prescribing of a placebo was a poor policy, neither saving the doctor's time nor benefiting the patient in the long run In this group the possibility of early tuberculosis, thyrotoxicosis, or new growth should be kept in mind There was the patient who came with organic symptoms, for whom the best treatment was a thorough clinical examination followed by explanation and reassurance Dr Fry emphasised the importance of patients referred to a psychiatric outpatient department receiving a thorough physical examination, for often such patients returned to their own doctor complaining that they had not been properly examined

In his own practice there were some 40 incurable neurotics, who attended his surgery about three times as often as other patients He referred about 8% of his psychiatric cases to hospital—a proportion comparable to the 10% referred by Watts[1] He thought that the general practitioner should treat the majority of his psychiatric patients, just as he should his obstetric cases, but should be aware of his limitations and not treat severe depression, psychopathy, or psychos Students should be taught more about the minor psychoneurotic conditions which they would encounter in general practice

Dr DENIS LEIGH said that at the Maudsley Hospital his unit was keeping a record of how the general practitioners referred patients to the hospital, and the recent figures agreed fairly closely with those given by Blacker[2] In 1950, for example, 696 doctors referred 1731 patients, 80% of the doctors and 86% of the patients were from the London area, 20% of the doctors and 14% of the patients from the country or abroad Taking the 1460 doctors practising in the south east and south west postal districts of London, it was found that 27% referred all the London patients, the remaining 73% referring none Of the 398 doctors in these two districts who referred patients, 168 referred 1 in the year, 170 referred 2–5, 43 referred 6–10, and 17 referred more than 10

MODE OF ACTION OF TROMEXAN

R. B. HUNTER
M.B.E., M.B., F.R.C.P. Edin.
PROFESSOR OF PHARMACOLOGY AND THERAPEUTICS

G. R. TUDHOPE
B.Sc., M.B. St. And.
ASSISTANT, DEPARTMENT OF PHARMACOLOGY AND THERAPEUTICS

UNIVERSITY OF ST. ANDREWS MEDICAL SCHOOL, DUNDEE

IT is now established that in the treatment of thrombo-embolic phenomena 'Tromexan' (ethyl biscoumacetate, bis 3-3'-(4 oxycoumarinyl) ethyl acetate) is as effective as, and less dangerous than, dicoumarol, over which it has two advantages. First, its action in reducing prothrombin activity is much quicker (18–48 hours, compared with 48–72 hours). Secondly, because of its more rapid destruction and excretion by the body, prothrombin activity and complications can be better controlled by varying the oral dosage. When the drug is discontinued prothrombin activity will increase sufficiently in 8–12 hours to control bleeding (Stirling and Hunter 1951).

The original studies of the effect of dicoumarol in man (Butt et al. 1941) showed a gradual fall of prothrombin activity in 48–72 hours. This suggests that dicoumarol might act by preventing the production of prothrombin by the liver, and that the delay of 48 hours is accounted for by the consumption of prothrombin already formed. In our early work with tromexan we noted the now well recognised rapid fall of prothrombin activity. In some of our experimental studies initial dosage of 1800 mg. brought about low levels of prothrombin activity in 9–12 hours. Two possibilities suggested themselves: either the life of prothrombin was much shorter than was originally thought, or tromexan acted mainly not on prothrombin but on some accelerator factor, interference with which caused the one-stage prothrombin test to give low estimates of prothrombin activity.

By different methods Owren (1944 and 1949) and Quick (1943) arrived at the conclusion that normal plasma contained a prothrombin accelerator which disappeared from stored plasma. The existence of this prothrombin accelerator—pro-accelerin (Owren 1949), prothrombin accelerator (Fantl and Nance 1946), factor V (Owren 1947)—is now accepted, and in this paper it is termed factor V. Warner et al. (1939a and b) have suggested that there was another prothrombin accelerator which is stable—co-thromboplastin (Mann and Hurn 1951), S.P.C.A. (Alexander et al. 1949), proconvertin (Owren 1947), factor VII (Koller et al. 1951), and in this paper it is referred to as factor VII. Owren (1950) and Koller et al. (1951) found that during dicoumarol therapy the concentration of factor V is practically unaltered but that prothrombin and also, more notably, factor VII are decreased.

Owren (1949) has also suggested that the one-stage Quick (1935) method of estimating prothrombin-time and the two-stage method of Warner et al. (1936) can be improved by the addition of factor V to the clotting system. Owren claims that this method gives an exact quantitative estimation of prothrombin regardless of the amount of factor V present.

We here set out information concerning: (1) the practical merits of Owren's and Quick's methods of determining prothrombin, using tromexan-treated plasma; and (2) the effect of factor V and factor VII on the clotting-times of tromexan-treated plasma.

PREPARATIONS

The term "tromexan-treated plasma" is used for plasma taken from a patient to whom tromexan has been administered. The addition of tromexan to plasma in vitro is without effect on coagulation.

Factor V (*Owren and Aas 1951*).—This is prepared from ox-plasma. Nine volumes of ox blood are mixed with one volume 2·5% (*w/v*) solution of potassium oxalate monohydrate. After being spun, the plasma is first clarified by passing it through an 18% asbestos filter-pad, and then it is passed through a filter-pad containing 50% asbestos, which Owren states will adsorb prothrombin and factor VII but allow the passage of factor V. The filtrate is neutralised to pH 7·3 by *N*/2 HCl, and then stored in small glass tubes at below −10°C.

Factor VII (*Owren and Aas 1951*).—Stored human serum is used as a source of this factor. A small amount of thromboplastin (3 ml. to 100 ml. blood) is added to normal human blood immediately after withdrawal, and the mixture is stirred. Prothrombin disappears almost completely in 30 minutes, and any remaining factor V disappears after storage for a week.

Thromboplastin.—A commercial preparation of rabbit brain is used—'Thrombokinase' (Geigy). One tablet (10 mg.) is crushed in a small test-tube and mixed with 2·5 ml. of normal saline. The suspension is warmed in a water-bath at 37°C for 10 minutes and is then ready for use.

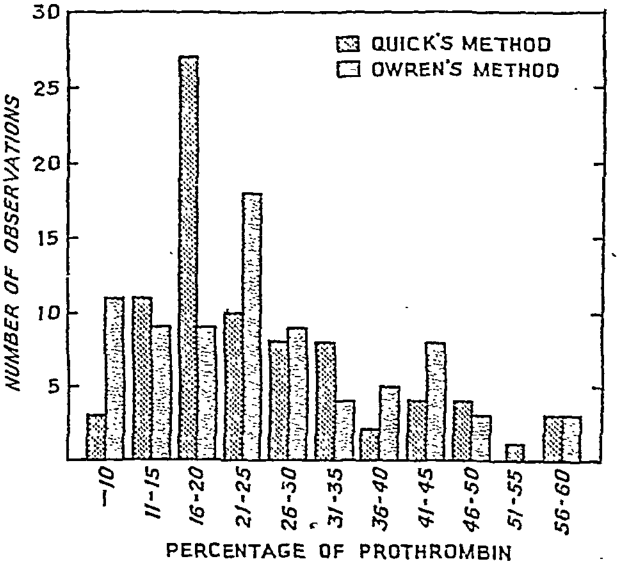
Barbitone Buffer Solution (*Owren 1949*).—This solution is prepared by adding 430 ml. *N*/10 HCl and 5·67 g. NaCl to 570 ml. 0·10 *M* sodium diethyl barbiturate and diluting the mixture with an equal volume of 0·9% NaCl solution.

METHODS OF PROTHROMBIN ESTIMATION

(1) *Modified Quick's Method.*—A mixture of 0·2 ml. plasma and 0·2 ml. thromboplastin suspension is incubated in a water-bath at 37°C for 5 minutes. Then 0·2 ml. 0·2% calcium chloride solution is added and the time required for clotting is measured.

The percentage prothrombin activity can be estimated for each plasma by the use of a correlation graph which is prepared from the average result obtained by estimating the clotting of at least ten dilutions of normal plasma.

(2) *Owren's Method.*—The plasma to be tested is obtained from oxalated blood by centrifuging, and is then diluted with the barbitone buffer solution to give 1 : 10 dilution of plasma. A small sample, 0·2 ml., is mixed with 0·2 ml. factor-V preparation and 0·2 ml.



Results of prothrombin tests by Quick's method and by Owren's method in 80 samples of tromexanised plasma.

capacity of the upper intestine is normal In the sprue syndrome, however, the intraluminar phase of fat absorption is normal and the defect is secondary to depression of the absorptive capacity of the upper small intestine[3] This can be demonstrated by estimating glucose and urea absorption, using the intraduodenal drip method, and by differential radiography, using flocculable and non flocculable barium sulphate It is confirmed by the fact that fat absorption becomes normal after the removal of wheat gluten from the diet of children with cœliac disease The subsequent administration of gluten causes return of the absorptive defect[4]

Osteomalacia in Steatorrhœa

Dr. Paul Fourman (Oxford) said that in this country osteomalacia is seen most often in patients with steatorrhœa The patients complain of pain and they may suffer spontaneous fractures Radiographs usually show generalised rarefaction of the bones, pseudo fractures may occur In blood taken from the fasting patient the serum phosphate is low, the phosphatase is raised, and the serum calcium is usually low The deficiency of calcium in these patients is the result of excessive fæcal loss Dr Fourman has found that vitamin D in a dose of 10,000 units daily by mouth does not improve the absorption of calcium Vitamin D given in the same dose parenterally, or in a dose of 50,000 units by mouth, improves the absorption of calcium if the calcium intake is high It does not improve absorption if the intake of calcium is only moderate, unless the excretion of fat in the fæces is at the same time reduced by reducing the fat in the diet With parenteral vitamin D and large doses of calcium by mouth these patients are cured of their osteomalacia, but the amount of calcium that they retain is small and the cure is slow These facts are explained as follows In patients with osteomalacia secondary to steatorrhœa there is a failure to absorb vitamin D The resulting deficiency of vitamin D is partly responsible for a failure to absorb calcium In addition there is a failure to absorb calcium because calcium may combine with unabsorbed fat in the intestine to form soaps Lastly, when these two faults are overcome it is seen that calcium is also directly involved in the absorption defect of steatorrhœa.

Interference between Antibiotics

Dr S D Elek and Dr Pamela Jewell said that it has been known for some time that the bactericidal action of pairs of antibiotics may be greater or less than that of each drug alone Conventional methods for studying the problem are however, laborious Dr Elek and Dr Jewell described a simple method for investigating the lethal effects of antibiotics and for demonstrating any interaction between one antibiotic and another This is an adaptation of a technique used by Lederberg and Lederberg for studies on bacterial genetics, it is applied as an extension of a sensitivity test in common use, and is simple enough to be included in the work of a routine laboratory

A sensitivity plate (Fairbrother and Martyn 1951) is incubated overnight A wooden block covered with sterile velvet is pressed on its surface and then pressed on a sterile plate In this way a constant proportion of any viable organisms is transferred free of antibiotic The number of colonies appearing after incubation of the second or replica plate reveals the proportion of organisms surviving the action of each drug

To detect antagonism two discs, each containing a different antibiotic are superimposed on the primary plate The lethal effect of the combination is compared with that of each drug alone To [illegible] discs are placed 1–2 cm apart and in the zon[illegible] have been exposed to the action of both dru[illegible] number of survivors is seen

Three pairs of antibiotics were tested by this method against 65 strains of common pathogens, including ten strains of enterococci from cases of endocarditis It was found that penicillin and aureomycin together showed either antagonism or no interaction, a combination of penicillin and chloramphenicol gave similar results Streptomycin and chloramphenicol, on the other hand, showed either synergism or no interaction In this way, for a newly isolated organism it may be said that the first two combinations are likely to be antagonistic while the third is likely to be synergistic Further work is required to assess the clinical importance of findings obtained by this simple method

Microculture of Mycobacterium Tuberculosis

Dr H M Rice and Dr F C Rowan (Nottingham) observed that a modification of Pryce's[5] microculture method for detecting *Mycobacterium tuberculosis*, applicable to concentrates of urine, pus, &c, as well as to sputum, gives a high proportion of positive cultures in 2–5 days Sensitivity tests can in many cases be reported in 5 days The method has been used with streptomycin, P A S, and isoniazid Löwenstein Jensen cultures are always made from the same material, so that nothing is lost if the micro method fails If it succeeds much time is saved The method is not laborious and requires no special apparatus 50% lysed horse blood has proved the best medium The use of pancreatin as a concentrating agent has led to more rapid and profuse growth on Löwenstein Jensen medium, compared with Petroff's method Often it has succeeded where Petroff's method has failed 8% hydrochloric acid is used to kill contaminants

Isoniazid Sensitivity of Tubercle Bacilli

Dr D A Mitchison said that strains of tubercle bacilli can be tested for isoniazid sensitivity by three methods

1 The *direct test*, in which sputum concentrate is placed on Löwenstein slopes containing a range of drug concentrations This technique is only possible where numerous bacilli are present and may waste medium

2 The *indirect test*, in which growth from a primary culture on drug free medium is inoculated on to a similar series of slopes

3 The *subculture test*, in which subcultures are made in Dubos medium and tested in this medium This method yields false results since highly resistant strains fail to grow or only grow slowly in Dubos medium

The indirect test, which Dr Mitchison recommended, should be carried out with an approximately standardised inoculum from young primary cultures, and the results should be read after 4 weeks The technique is still not satisfactory since repeat tests yield gross discrepancies in about a third of resistant strains A medium more satisfactory than Löwenstein's is required for the growth of resistant strains

Sensitive strains are inhibited by 0 2 µg isoniazid per ml in Löwenstein medium, though a few colonies may grow in this and higher concentrations Strains growing on 1 µg per ml are likely to be resistant since animals infected with such strains do not respond to treatment with a higher dosage of isoniazid than is used in man Since strains with a higher degree of resistance appear avirulent in guineapigs, the results of tests on strains isolated via guineapigs cannot be considered reliable

Culture of Tubercle Bacilli and Sensitivity Tests

Dr W K Taylor (Godalming) said that in routine work concentration methods are valuable, but with watery sputa it is much more satisfactory to pick out purulent fragments Oxalic acid may affect acid fastness Papain is a valuable liquefying agent, and its addition should be followed by that of 5% oxalic acid This is the most useful disinfectant, no neutralisation, and only one centrifugation, is necessary Flotation methods are efficient but tedious, possibly dangerous to staff, and generally unsuitable for subsequent culture In a small series, about 25% of the negative smears from tuberculous patients gave a positive result with ligroin flotation The increase of sensitivity tests is making great demands on incubator capacity, but this difficulty can be overcome to some extent by using a four bottle technique with 0, 1 [illegible] and 100 µg streptomycin per ml in Dubos medium in screw cap bijou bottles This gives three degrees of resistance—slight, clinical, and marked—which simplifies interpretation of reports

Acute Hæmorrhagic Leuco-encephalitis

Prof T Crawford said that hæmorrhagic leuco encephalitis was first recognised in 1940 by Weston Hurst in Adelaide, and only seven examples have been recorded Three typical examples have, however, been seen at St George's Hospital London, in a two year period The condition occurs chiefly in males in the third and fourth decades There is often a prodromal upper respiratory infection, followed, perhaps after a brief recovery, by the neurological stage which is fatal within a few days The cerebrospinal fluid shows an increased cell count of up to three or four hundred per c mm—principally polymorphs—and there is a polymorph leucocytosis in the blood The naked eye lesions consist of petechial hæmorrhages limited to the white matter and usually maximal in one or both cerebral hemispheres They extend down a variable distance and may involve cerebellum and pons The most affected parts are œdematous and discoloured Microscopically the white matter shows ball and ring hæmorrhages, serous and cellular exudate, rich in polymorphs, fibrin impregnation in and around the vessel walls, and fibrin exclusively, for when normal plasma was mixed with purified prothrombin in various proportions, the conversion rate was independent of the prothrombin concentrations, but paralleled directly the concentrations of the accessory factors."

The majority of workers in this field would at the present time accept the view that the various factors mentioned are prothrombin accelerators. Biggs and Macfarlane (1953a and b) and Biggs et al. (1953), however, have recently reported very good evidence suggesting that five factors are concerned in thromboplastin generation—the platelets, factor v, factor vii, antihæmophilic globulin, and the Christmas factor (Biggs et al. 1952). They suggest that brain thromboplastin, whether it be derived from animal or human source, is not really thromboplastin at all but is a mixture of antihæmophilic globulin, platelet factor, and the Christmas factor. Thromboplastin preparations, therefore, such as we have used in this study do not contain complete thromboplastin but are deficient in both factor v and factor vii. It is only on the addition of these factors that thromboplastin formation proceeds, and this reaction takes a short but definite time—10–12 seconds. The use of brain thromboplastin reveals factor-v and factor-vii deficiency as well as prothrombin deficiency. Thus thromboplastin generation does not take place quickly in tromexan-treated plasma because of deficiency of factor vii. There is also evidence (Koller et al. 1951, Owren and Aas 1951, Biggs and Macfarlane 1953a and b) that prothrombin is reduced in amount by the administration of dicoumarol or tromexan; but this reduction is neither so rapid nor so great as that of factor vii, particularly with tromexan.

SUMMARY

Evidence is described which supports the view that tromexan acts on the mechanism of blood coagulation similarly to dicoumarol, and that its action is principally on factor vii.

A comparison of Quick's and Owren's methods of estimating "prothrombin" indicates that Quick's one-stage method is suitable for routine use.

Reference is made to recent views on thromboplastin generation.

We are grateful to Dr. Ann C. Donald for assistance in carrying out a number of estimations and to Mr. E. A. Asher, of Pharmaceutical Laboratories Geigy Ltd., for supplies of thromboplastin. Part of the expenses of the research were defrayed by a grant from Pharmaceutical Laboratories Geigy Ltd., Manchester.

HÆMORRHAGIC DIATHESIS DUE TO ABSENCE OF CHRISTMAS FACTOR*

S. VAN CREVELD
M.D. Groningen
PROFESSOR OF PÆDIATRICS

M. M. P. PAULSSEN
Pharm.D. Amsterdam
HEAD OF BIOCHEMICAL LABORATORY

PÆDIATRIC CLINIC, UNIVERSITY OF AMSTERDAM

LATELY some cases have been reported of a hæmorrhagic diathesis which clinically resembled hæmophilia but in which there was no deficiency of the antihæmophilic factor or any coagulation factor previously recognised. This condition has been attributed to the absence of another coagulation factor recently discovered in the plasma. The disease has been described by Aggeler et al. (1952), Schulman and Smith (1952), Biggs et al. (1952), and Poole (1953), and the familial hæmorrhagic disorder described by Koller et al. (1950) is probably the same. Biggs et al. (1952) named the condition Christmas disease after their first patient and described seven cases.

We report here a case of Christmas disease which illustrates the difference between it and another hæmorrhagic diathesis (hypoproconvertinæmia) which has also been recently described for the first time.

THE CASE AND THE DIAGNOSIS

A boy, aged 10 years, the only child of healthy parents, showed the first signs of a hæmorrhagic diathesis after an injury at the age of 15 months. Before this trauma, however, his parents had noticed that he was easily bruised.

This first hæmorrhage due to trauma was followed by many severe ones, especially in midsummer and midwinter. The hæmorrhages, especially from the nose, often began and stopped suddenly. Not rarely a hæmorrhage occurred some time after a preceding hæmorrhage had apparently stopped. The patient had also repeated hæmorrhages into the joints (ankles and knees), but there was no ankylosis of these joints or restriction of their function, such as develops in hæmophilia. Dr. G. J. van Lookeren Campagne, who sent us this patient, had many years ago found a prolonged coagulation-time and had diagnosed hæmophilia. No hæmorrhagic diathesis could be traced in the family.

When admitted to the Children's Clinic the boy had (table I) a much prolonged coagulation-time of the venous blood; normal values for bleeding-time, blood-clot retraction, fibrinogen content, and thrombocyte-count; normal capillary resistance; and insufficient consumption of prothrombin on coagulation.

TABLE I—RESULTS IN DIFFERENT DETERMINATIONS IN BLOOD

—	Patient	Normal values
Clotting-time	Several hours	10–14 min.
Bleeding-time (min.)	2–5	2–5
Clot retraction	Normal	—
Fibrinogen	Normal	—
Number of platelets	Normal	—
Capillary fragility	Normal	—
Residual prothrombin in serum (units per ml.)	220	<10
Prothrombin-time (Quick) ..	13 sec.	13 sec.
Prothrombin in plasma (units per ml.)	340	275–350
Plasma Ac-globulin (units per ml.)	15	13–17
Proconvertin	60 % of normal	—
Anticoagulant	Absent	

The boy was not (we concluded) suffering from hæmophilia, because:

(1) His plasma in various dilutions (table II) exerted a normal coagulation-promoting activity on the blood of a known hæmophiliac with a greatly prolonged coagulation-time.

* This work was supported by a grant from the Nederlandse Organisatie voor toegepast Natuurwetenschappelijk Onderzoek (Dutch Organisation for Applied Scientific Research).

Mrs Klein's theory by some psycho-analysts in this country and the United States

Mrs Riviere, who edits it, writes an introduction which aims to rebut the objections made with varying force by Edward Glover, Sylvia Payne, Edward Bibring, and other psycho-analytic critics (who are, however, hardly mentioned by name) The contributors to the volume, who are, or were, strong supporters of the Kleinian theory, speak not only for themselves and a few contemporaries but also for a large proportion of the younger psycho analysts trained in London during the last twenty years The views put forward are technical and recondite, especially in the passages describing destructive and other fantasies which babies are supposed to entertain during the first few months of life Few who are not psycho analysts or "analysands" are likely to read the book with understanding and appreciation

Scope and Interpretation of the Commoner Biochemical Tests

South African Institute for Medical Research Johannesburg 1952 Pp 120 10*s* 6*d*

To many doctors the interpretation of biochemical tests is a continual difficulty while there are a number of larger works (e g , Peters and van Slyke) dealing with interpretation in detail, there is no simple book giving interpretation for general physicians and students This small volume from the biochemical department of the South African Institute for Medical Research is a worthy effort to fill the gap, at a very reasonable price

After a very brief introduction emphasising the important concept of a "normal range" rather than a normal value, it describes, under headings arranged alphabetically, the normal values for various blood constituents, and the changes which may be expected in disease, followed by sections on cerebrospinal fluid, fæces, gastric analysis, urine, liver and kidney function tests, and water and electrolyte balance Finally, there is an 18 page summary of normal values and the principal variations in disease, and an adequate index

The various paragraphs give clear information to a doctor who wants a simple explanation of what a result signifies, and usually the information given is fully adequate but the alphabetical arrangement does produce difficulty at times and leads to such subjects as Calcium, Phosphorus, and Phosphatase being widely separated, so that a rather long table giving the calcium, phosphorus, and phosphatase figures together is needed to correlate the findings In a future edition, it might be better to confine the alphabetical order to the summary and arrange the matter in the body of the book more systematically

The amount of space given to gastric analysis compared with that for water and salt metabolism seems disproportionate in 1953, and in the latter section, though "milli equivalents" are briefly mentioned, all other figures given are in volumes or milligrammes Surely at the present time milli equivalents should be used in the text and not merely put in as an academic curiosity

In the short chapter on liver function, it would probably be preferable if fewer tests were discussed more critically and in greater detail It is only too easy to get lost in a multiplicity of tests

Vitamins and Hormones

Advances in Research and Applications Vol 10 Editors ROBERT S HARRIS, professor of biochemistry of nutrition Massachusetts Institute of Technology , G F MARRIAN, F R S , professor of medical chemistry, University of Edinburgh , KENNETH V THIMANN professor of plant physiology, Harvard University New York Academic Press London Academic Books 1952 Pp 421 64*s*

WHEN a periodical of this kind has been running for ten years and the editors can say that it "continues to meet with acceptance and almost complete absence of adverse comment" there is little doubt that it has made a niche for itself

Volume 10, they remark is concerned with hormones rather than with vitamins but most of the articles seem to deal pre eminently with nutrition Thus Eric K Cruickshank, writing on dietary neuropathies, deals with beriberi, the painful feet syndrome Wernicke s encephalopathy , and other allied diseases—all good reading for clinical men Albert E Sobel discusses the absorption and transport of the fat soluble vitamins and Ernest Beerstecher the nutrition of the crustacea, of which very little seems to be known Other articles with a general bearing on nutrition cover the pituitary experimental glycosuria, the influence of the corticoid hormones on enzymes concerned with carbohydrate metabolism, steroids and tissue oxidation, and hormone assays in obstetrics and gynæcology The authors form an international coterie, for three hail from Switzerland, one from Jamaica, two from Scotland, and the remainder from the United States

Scientific Study of Personality

H J EYSENCK, PH.D London Routledge & Kegan *Paul 1952 Pp 320 30s*

THIS work bears constant witness to its twofold origin it is rigorous in method and thought because it comes from a department of psychology with a strong statistical bias , and, since Dr Eysenck is reader in psychology in the Institute of Psychiatry at the Maudsley Hospital, the investigations are everywhere indebted to the clinical material, stimulation, and validating judgments which such a medical centre affords Dr Eysenck's aim has been to discover the main measurable features of personality and to define them by means of quantitative experimental procedures, leaving no room for ambiguity His previous book, *Dimensions of Personality*, had the same aim but did not range so widely through normal and abnormal subjects, juveniles and adults He has organised a large programme of research, consistently related to his aim , and the results are woven, with those of other psychologists working in the same institute, into an intricate yet distinct and coherent pattern In many passages the exposition is provocative, and to some readers provoking, but in a field of knowledge dappled and sometimes wholly darkened by clouds of vagueness and compromising evasion, it is refreshing to have an author's standpoint and intention made quite plain It is likely that the findings reported here will contribute to a more constant diagnostic classification of mental disorder, and a more exact description of personality than we have now but even if this should prove an over-hopeful view, the argument developed in the book will undoubtedly serve to clarify some obscure stretches in our understanding of personality and mental illness, and the methods it describes will have a continuing part in further research

PROFESSOR OF SURGERY, UNIVERSITY OF WALES

AN aortic arch may be present in the supraclavicular region and clinically resemble an aneurysm of the subclavian, carotid, or innominate arteries. In mistake for such it may be ligated with fatal results, as has probably been done on several occasions (Beavan and Fatti 1947). This accident nearly happened in the following case, but fortunately our suspicions were aroused and later strengthened by the late C. M. West, then professor of anatomy at the Welsh National School of Medicine, whom we invited to see the patient and who was present at the operation and suggested that the large pulsating vessel was a high aortic arch.

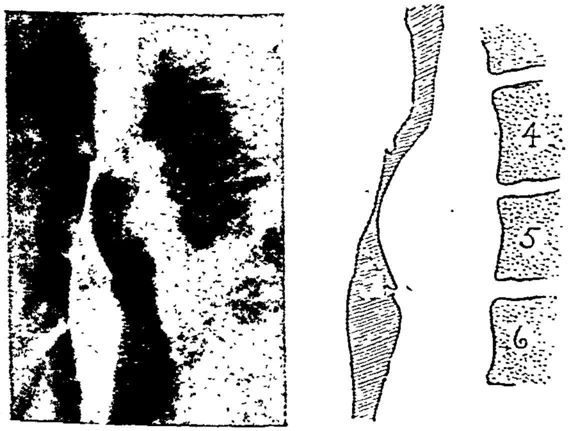

Fig. 1—Left anterior oblique view, after barium swallow, of concavity produced by aorta passing behind œsophagus at level of 4th and 5th thoracic vertebræ.

CASE-RECORD

In September, 1937, a boy, aged 5 years, was investigated in the children's department of the Cardiff Royal Infirmary (Dr. A. G. Watkins). A pulsating swelling in the lower part of the right side of the neck had been noticed three years previously and had not altered appreciably during that time. His mother described him as "very delicate and catches cold easily; is not lively and always wants to rest; his lips go blue at times and he becomes short of breath on walking to school." Past illnesses were scarlet fever, diphtheria, and measles. There was an oval tumour, measuring 1½ in. in its longest axis, in the region of the right common carotid artery; it exhibited an expansile pulsation with a palpable thrill and a bruit on auscultation. The right radial pulse was normal. On the left side axillary pulsations were faintly perceptible, but no pulsations were felt in the brachial, radial, or ulnar arteries. The blood-pressure was 95/64 mm. Hg in the right arm and could not be measured in the left. A murmur heard over the swelling was propagated to the base of the heart. Heart sounds were otherwise normal, and the heart was not enlarged. The pulses in the femoral arteries were palpable and equal on both sides. Electrocardiograms showed normal tracings, and radiography showed minimal cardiac enlargement with slight widening of the upper mediastinal shadow.

First Operation

In August, 1939, he was readmitted with dyspnœa and cyanosis on exertion, and diplopia of two years' duration. The pulses in the arteries of the upper limbs were unchanged, and the blood-pressure on the right side was 95/65 mm. Hg. On Aug. 9, under general anæsthesia, the swelling was exposed through a transverse incision in the lower part of the right side of the neck. The jugular vein was seen to be greatly enlarged and lying to the outer side of a grossly enlarged arterial trunk which was in the position of the common carotid artery; there was no arteriovenous communication. The arterial trunk extended to the hyoid bone, where it formed acutely an anteroposterior arch, with its afferent loop lying slightly internal to its efferent loop. From the apex of the arch the internal and external carotid arteries had their origin. A nerve descending from high in the neck was an external relation of the arch and was thought to be either the right superior laryngeal nerve or the right vagus, but it was considered inadvisable to dissect any further to establish its identity, and the wound was closed.

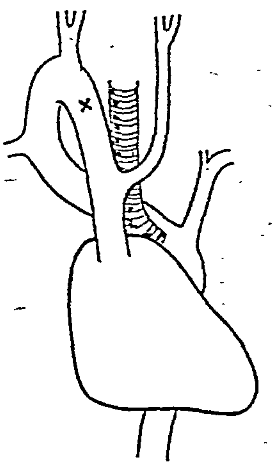

Fig. 2—Suggested disposition of great vessels: lateral pressure at X abolished both femoral pulses, both radial pulses, and right carotid pulse.

Second Operation

In January, 1940, the deep cervical fascia overlying the prominent vessel was reinforced with donor fascia in the form of mattress sutures, the free ends of the fascia being sutured diagonally over the surface. At this operation it was noted that compression of the vessel stopped the femoral pulses.

Further Investigations

In May, 1950, the patient was readmitted having fainted twice while at work as a fish-fryer and having had headaches on reading for any length of time. The cervical swelling was now about 3 in. long and 1½ in. wide. The trachea was displaced to the left of the midline. Pulsation in the left radial artery was present but considerably weaker than on the right side. Blood-pressure in the right arm was 112/86 mm. Hg, in the left arm 92/84. There was no evidence of cardiac enlargement. The right palpebral fissure was narrower than the left. There was no difference in the skin-temperature in the right and left sides of the face, and power in the arms was equal.

On June 2, 1950, 20 ml. of 35% diodone was injected into the prominent cervical vessel. Pain was felt by the patient in both arms simultaneously and in the head. Dispersion of the radio-opaque substance was too rapid, however, to enable any definite conclusions to be drawn from the X-ray exposures. Electro-encephalography showed scattered low-voltage theta waves in all the leads, intermingled with alpha rhythm, but hyperventilation had not much effect on the record, which was considered to be outside the normal range. For the first time a temperature difference was noticed, the right hand being 5 degrees warmer than the left.

Radiography after barium had been swallowed showed a smooth constant concavity in the œsophageal outline at the level of the 4th and 5th thoracic vertebræ (fig. 1). We presume that this appearance is due to the aorta passing behind the

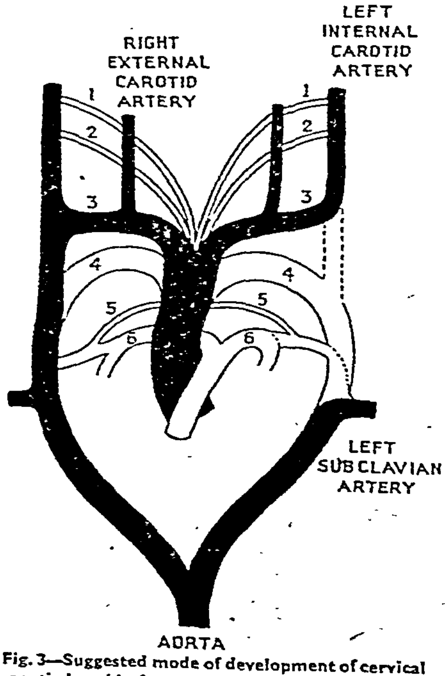

Fig. 3—Suggested mode of development of cervical aortic knuckle from primitive vascular pattern.

and thereby they expose a fiction which has sustained the opponents of analgesia since the days of SIMPSON The old saying that "after all they forget the whole thing" contains a germ of truth which relates only to the quality and perhaps the full intensity of pain Recollected pain can seldom be described, for it cannot be recalled in the sensorium as can visual or auditory images, and at a second or later labour women are sometimes heard to say "I remembered that it was bad last time, now I remember how awful it was" FREEDMAN's paper also underlines the fact that childbirth is especially remembered as an important event, though this memory, which is the pivot to less important ones, may be distorted by self-justification and by later experience

The patients studied by the Yale workers were all participating in the Newhaven "natural childbirth" programme[23] "Natural childbirth" is an attractive but misleading title, for the main aim of the Newhaven and similar schemes—for example, that of Prof W C W NIXON at University College Hospital, London—is to make delivery as easy and tolerable as possible within the limits of safe analgesia Much skill is required to ensure really effective analgesia in labour this cannot always be provided in hospital, let alone in the home These schemes, though differing in detail, consist essentially of two parts first, a psychophysical preparation for childbirth, and secondly, a labour-ward technique The first part is directed at giving the woman confidence in her own powers—the sort of self-confidence that was signally lacking in the days when society and the medical profession kept her in ignorance Thus lectures on various aspects of normal childbirth are combined with a small amount of physical training The lectures cover the development of the child, the process of birth, breast-feeding, and baby-craft The physical training, carefully dovetailed with the lectures, consists in postural adjustment to the strains of pregnancy, relaxation, and breathing exercises With the exercises evolved by the late HELEN HEARDMAN[24] the woman also learns pelvic rocking, and accustoms herself to the lithotomy position She should also get to know the hospital and its staff and familiarise herself with the analgesic apparatus NIXON[25] thinks that as regards labour the most important part of the programme is the labour-ward technique In the labour ward the woman is encouraged to rely on her own powers, by making use of the things she has learnt, and she is never left alone—thus averting an experience that has frightened many Like any other prophylaxis this programme does not deal with established disease As MANDY et al[26] rightly point out, the seriously disturbed woman needs treatment as well as 'natural childbirth' sexual disturbances, for example, which are widespread in our population and can have important sequelæ in labour[27–29] are not dealt with in the classes

Most of the critics of 'natural childbirth' programmes tend to assess their value purely in terms of the effect of the classes on the course of labour[26 30], and commonly they judge this only in terms of mechanical factors, ignoring emotional factors Perhaps this is partly the fault of some who, writing on the physiotherapeutic aspects, seem to have concentrated on statistics covering mechanical factors, in an attempt to appeal to the "obstetrician-in-the-street" There has been far too little research into emotional aspects and psychophysical mechanisms, and virtually no research into either the need for antenatal classes or their effects WOODWARD,[31] however, has inquired into the attitudes of 100 pregnant women who were attending antenatal clinics but not classes in natural childbirth She found that in the life of a woman loneliness and apprehension were ordinarily at their peak from the fourth month of her first pregnancy, when she leaves work and faces a lonely existence, a lower income, and the unknown terrors of confinement WOODWARD's findings would lead one to suppose that women who have attended classes would come to labour better prepared after a happier and less tense pregnancy

Regimentation of the patient and dependence by her on an authoritative figure has long been the basis of conventional maternity obstetric practice[27], but it has no place in natural childbirth The divergence between the two systems is evident at every medical discussion of the subject[30] "Natural childbirth" programmes represent one of the first attempts to practise a preventive medicine that recognises the unity of body and mind, by combining health education, group discussion, participation, and psychological techniques This promising approach, which GRANTLY DICK READ[32] has done much to promote, has captured the attention of the public, and is thus being given a fair chance to develop, and authority, which is playing its traditional rôle, is failing to put the clock back

Blood-clotting

AT last year's International Conference of Hæmatology, held in Argentina, the research-workers on blood clotting held a separate meeting to discuss their difficulties Such a meeting was necessary because progress towards a better understanding of blood clotting and its disorders was becoming obscured by a fog of nomenclature, everybody seemed to have their own name for the various "factors" concerned in clotting, and new ones were being added before the old ones were properly understood Some efforts towards resolving the confusion have now been made, and it is clear that the factors are nothing like so numerous as the literature might suggest The fifth conference on blood-clotting held by the Josiah Macy, Jr, Foundation in New York set up a committee which has published[33] a list of synonyms for the so called prothrombin accelerators—factor V of Owren and factor VII of Koller STEFANINI,[34] in a review of present ideas, has compiled a more comprehensive list He points out that most workers at present agree that blood-coagulation has three stages (1) activation of thromboplastin, (2) conversion of prothrombin to

Preliminary Communication

EFFECT OF CHOLINE ON CERTAIN FORMS OF ŒDEMA

THE theory of Starling (1896) and Schade (1935) states that transudation of tissue fluid is due mainly to variations of hydrostatic and colloid osmotic pressure. In those conditions of disordered physiology which give rise to œdema not all the observed facts can be explained by this theory. Thus Govaerts (1947) proved that a certain relation exists between the colloid osmotic pressure and the albumin/globulin ratio in cardiac or nephrotic œdema, but he did not find it in hunger œdema. Sinclair (1947) could not demonstrate a significant difference in plasma-protein level between hunger patients with and without œdema; and Keys (1947, 1950), using Tiselius's electrophoretic method, observed no difference in serum-protein fractions in these patients. On the other hand, some patients with very low plasma-protein levels have no œdema.

We have recently seen a woman, aged 39, with anorexia nervosa, who was much underweight (height 5 ft. 6 in., weight 6 st. 2 lb.) and had a very pronounced hypoalbuminæmia (total protein 4·86 g. per 100 ml.; albumin/globulin ratio 1·0, phospholipid 10 mg. per 100 ml.). Heart, blood-pressure, and circulation-time were normal. There was not a trace of œdema, which (according to Starling's theory) she should have had.

BIOCHEMICAL CHANGES IN CASE 2

Date	Total lipid (mg. per 100 ml.)	Phospholipid (mg. per 100 ml.)	Serum-albumin (method of Majoor) (g. per litre)	Flocculation test* (ml.)	Urinary protein (g. per litre)	Œdema

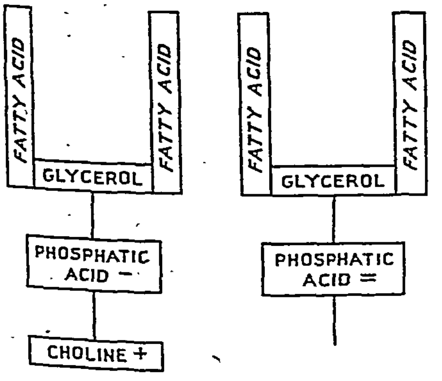
* A flocculation test with $HgCl_2$ solution, expressed in ml. necessary to produce flocculation. Normal is 2 ml., corresponding to a normal albumin/gamma-globulin ratio.

However, during the famine period in Western Holland in the late war it was found that, although certain hunger patients with œdema had hardly any other biochemical abnormality, they did have a low blood level of lipid phosphorus (Neumann 1946). This was also observed by Feigl in 1917 during the first world war (Feigl 1920). In both periods the daily rations contained only small amounts of methionine, choline, and lecithin, owing to the lack of certain foods—e.g., bacon (Maase and Zondek 1920), soya, meat, and butter (Gounelle 1947). All of these foods are rich in phosphatides, and we know that methionine is transformed to choline in the body. It may well be that choline is an essential factor in hunger œdema; so we tried the effect of it in some cases of œdema.



PHOSPHATIDE PHOSPHATID ACID

Fig. 1—Relation of phosphatide to phosphatid acid.

CASE-RECORDS

Case 1.—A man, aged 70, with hunger œdema, had gone without meat, butter, eggs, milk and cheese for months and had slowly developed œdema. Physical examination revealed no abnormality. His heart, blood-pressure, and circulation-time were normal. Liver function was almost normal, but the serum-albumin level was low, 2·8 g. per 100 ml., with gamma-globulin 2·7 g. per 100 ml. The serum-lipid phosphorus level was 8·1 mg. per 100 ml. (total lipid 530 mg. per 100 ml.). We therefore gave him 3 g. of choline chloride daily by mouth, and his œdema entirely disappeared in fourteen days. There was no change in his serum-protein during this period.

Case 2.—A bricklayer, aged 54, who developed œdema had severe albuminuria (22 g. per litre). The urinary sediment contained a few leucocytes and casts. The heart and blood-pressure were normal. The basal metabolic rate was −7%; urea clearance was 76%; a phenolsulphonphthalein test gave 71%; urine sp. gr. 1·021. The serum-protein level was very low—4·1 g. per 100 ml. (albumin 2·1 g., gamma-globulin 2·0 g.). The diagnosis of nephrotic syndrome was clear. Treatment with a high-protein diet, protein hydrolysate, and blood-transfusions failed to arrest the steady increase in œdema. His weight went up from 67 to 90 kg. (10 st. 7 lb. to 14 st. 2 lb.). Neither thyroxine nor testosterone injections had any effect. The serum-lipid level rose to 1170 mg. per 100 ml., and the serum-cholesterol to 355 mg. Lipid phosphorus decreased (7·8 mg. per 100 ml.) and we therefore again tried choline therapy. On this treatment, although the serum-albumin level remained low, and in spite of loss of protein in the urine, the total serum-lipid level fell, the serum-lipid phosphorus rose, and œdema disappeared. After the disappearance of the œdema the protein loss in the urine became negligible, with a corresponding increase in the serum-albumin (see table). Phenolsulphonphthalein test and urea clearance were 70% and 43% at the beginning of therapy and at the end of it 50% and 50% respectively.

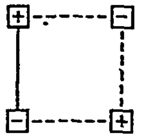


Fig. 2—Tricomplex of Bungenberg de Jong (1949).

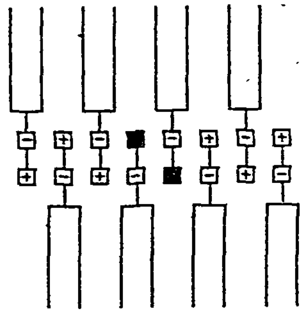

Fig. 3—Model of cell membrane (Bungenberg de Jong 1949).

DISCUSSION

The disappearance of œdema in these two cases might be explained as follows.

Choline is a lipotropic factor beneficial to liver function. Deficiency of choline may lead to a qualitative change in serum albumin, producing œdema. Suggestive evidence of this has been collected by Williams (1951), though it must be admitted that œdema seldom occurs in other cases of liver injury in which the serum-protein levels are low. Alexander and Engel (1953) found that choline prevented œdema in rats fed on low-protein diets, and that lack of choline led to fatty and cirrhotic livers, with the appearance of œdema.

According to Bungenberg de Jong (1949) the cellular wall contains a tricomplex of phosphatide (ampho-ion), phosphatid acid (negatively charged ion), and an exchangeable positively charged ion—e.g., Ca^{++}. Now the phosphatid acid is phosphatide which has lost its choline group, and the availability of choline will effect the ratio between phosphatide and phosphatid acid, and therefore the permeability of the cell membrane (figs. 1, 2, and 3)—e.g., of the cells of the capillary endothelium.

The effect of choline on cardiac œdema is still under investigation.

SUMMARY

The effect of choline chloride has been observed in two cases of œdema, one due to starvation and the other has also drawn attention This condition appeared clinically to be classical hæmophilia, but the missing factor proved to be not the antihæmophilic globulin of plasma but a serum factor, possibly identical with the "plasma thromboplastic component" described by some American workers[42,43] And this week Professor **VAN CREVELD** and Dr **PAULSSEN** describe another example of this condition **BIGGS** et al called the disease by the name of their first patient, which happened to be Christmas, and the factor was called the Christmas factor **BIGGS** and **DOUGLAS** found that plasma adsorbed with alumina still contained antihæmophilic globulin in addition to factor V, and normal serum contained Christmas factor in addition to factor VII These four factors together with a fifth—blood platelets—react together in the presence of calcium salts to form a labile thromboplastin Deficiency of any of these factors produces a coagulation defect that gives an abnormal result with thrombin-generation tests, and is reflected clinically in a hæmorrhagic syndrome

For thromboplastin-generation tests a mixture of alumina plasma, platelet suspension, and diluted normal serum is used to provide the five factors When calcium chloride is added, clotting is initiated As with the other tests, specimens are removed at intervals, and this time they are added to a recalcified platelet-free "substrate normal plasma", and from the clotting-time of this mixture a quantitative estimate of the thromboplastin formed can be made In hæmophilia a mixture of the patient's alumina plasma with normal platelets and serum shows in this way grossly defective thromboplastin generation, but in Christmas disease a similar mixture gives normal results If a mixture of normal alumina plasma and platelets and patient's serum is used, it is Christmas disease and not hæmophilia that gives the defective thromboplastin generation **BIGGS** and **DOUGLAS** were able to test a patient with abnormal giant platelets (thrombo asthenia), and this patient's platelets, mixed with normal alumina plasma and normal serum, gave abnormal results in this test The test therefore makes a clear-cut differentiation between classical hæmophilia and Christmas disease it will detect hæmophilia in patients who are so mildly affected that the whole-blood clotting-time and the prothrombin-consumption tests are normal It is unfortunately complicated, demanding much careful preparation of test materials and quite unusually complicated laboratory gymnastics during its performance For example, at one stage the technician has two graduated Pasteur pipettes each containing 0 1 ml of test solutions, and he must discharge them simultaneously into a tube containing 0 1 ml of substrate, start a stopwatch at the same time, and observe a clotting reaction that may be complete in 10 seconds Such tests are not likely to be popular, even in research laboratories, and are much too time consuming for routine use So it is fortunate that for most cases the tests at present in daily use will suffice The use of the Quick one-stage clotting test (the doubts about the "prothrombin" it measures have we suppose, made "prothrombin-time" out of order) is still the best way of controlling the factor-VII deficiency caused by anticoagulants Most cases of hæmophilia can be detected by a combination of the whole blood or recalcified-plasma clotting-time and the prothrombin consumption test The only therapeutic importance of the distinction between classical hæmophilia and Christmas disease is that hæmophilia must be treated with blood or plasma not more than one day old whereas serum can be used for Christmas disease The mild form of hæmophilia described by **GRAHAM** et al[44] in 14 members of a single family is due to deficiency and not complete absence of the antihæmophilic globulin It is clear that the identification of cases of hæmorrhagic disease that do not conform to the commoner syndromes must be left to the few special centres where the more complicated investigations are in regular use In no field does attention to technical minutiæ count for more, and it is waste of time to carry out occasional tests of this type Research centres will now have, in the thrombin generation test, a not too complicated tool for objective assessment of proposed remedies for hæmophilia

The story of coagulation continues to be unfolded at a brisk pace, which makes the attempt that is now being made to control nomenclature all the more necessary To many of those who are grappling with the latest chapters, uninformative eponyms, however seasonable, are less welcome than a definitive title and another trap to be avoided lies in the use of a name that has already been given to another condition For instance, **HOUGIE**[45] has lately used the name "pseudohæmophilia" to describe a syndrome due to a circulating anticoagulant, but this name has already been in use for some years to describe a hereditary capillary abnormality, also known as constitutional thrombopathy or von Willebrand's syndrome It would be a pity if the editing of this complicated but important story was offset by the reintroduction of disguised or equivocal characters

Annotations

TREATMENT OF HYPERTENSION

THERE is no satisfactory treatment for essential hypertension, and none can be expected until more is known of the mechanism of raised peripheral resistance At present we wring what we can from a wide range of remedies Sympathectomy has passed through many vicissitudes, from enthusiastic reception to denial that it significantly benefits any form of hypertension[47] Now, however, its place has become stabilised Thorpe et al[48] reviewed 500 cases of bilateral thoracolumbar sympathectomy and found statistically significant benefit in "group 4" (papillœdema) cases only Morrissey et al,[49] who have reviewed 122 cases, take a rather less pessimistic view, and are prepared to recommend it to patients with disabling symptoms such as severe headache, without advanced retinal changes They emphasise, however, that in malignant hypertension a trial must first be made of 2–3 months' complete rest and adequate treatment with hypotensive drugs They note that symptoms—for example, headache—may be substantially relieved by sympathectomy even if this fails to lower blood pressure Possibly in adopting sustained lowering of blood pressure as the sole criterion of efficacy, we are taking too narrow a

Since he had begun doing domiciliary visits, the number of doctors referring only 1 patient had fallen, and the number of those referring 2–5 had risen. He felt that the domiciliary visit offered the hospital consultant an invaluable opportunity for learning about the psychiatric problems of the general practitioner and for seeing the patient against his home background.[3] He had now made contact with all the doctors in the area who referred their patients.

Referrals came under five headings: depressions, neuroses, organic cases, marital problems, and social problems. He felt that general practitioners should be taught to diagnose the depressed patient earlier. There was difficulty in selecting the neurotic case to be referred to the consultant, who should bear in mind that the general practitioner usually sent this patient along for treatment, not just for another opinion. He did not think that the general practitioner should undertake systematic psychotherapy. Many of the chronic neurotics and the organic cases were referred because they were a nuisance to the busy practitioner. Social-problem cases were better dealt with at hospital where the psychiatric team, including the psychiatric social worker, were more qualified to advise on the facilities. Most patients with marital difficulties should be referred to a solicitor rather than to the psychiatric consultant, for few of them could be helped. He thought that psychiatric diagnostic terms were too complicated for the general practitioner, and that a committee of consultants and practitioners should draw up a simpler list. The psychiatrist embarking on domiciliary visits should be well qualified in general medicine and fully abreast of modern knowledge. He thought that students should be taught more of the simple neuroses. A large number of psychiatric cases went unrecognised in general practice because of the practitioner's ignorance of, or his prejudice against, the psychiatrist and the psychoneurotic patient.

Dr. C. A. H. WATTS said that his figures agreed largely with those of Dr. Fry, although people in his practice were not quite so neurotic. He thought that 50% of the neurotics were treatable by the practitioner, and disagreed with Dr. Leigh about the practitioner not being fit to undertake simple psychotherapy. He himself referred about 10% of his psychiatric patients to a consultant—an average of 15 cases per annum. If Dr. Fry's figures for a 4500 practice with about 500 psychiatric cases were representative of the whole country, this would give a total of 5 million cases; and it was obviously impossible for the psychiatric services to cope with this number.

Dr. GERALD GARMANY thought that the Geneva nomenclature was quite clear and no more complicated than that of the blood disorders or orthopædics. He disagreed, like Dr. Watts, about Dr. Leigh's exclusion of the marital cases, many of which benefited by coming under the attention of the hospital psychiatric team.

Dr. SAWLE THOMAS thought that the difference between the hospital-trained psychiatrist and the practitioner was that the former was more interested in diagnosis and the latter wanted something done for his patient. He had done about 130 domiciliary visits in 1952; about 30% of the patients had been depressives, and another 30% schizophrenics, who were much rarer in Dr. Denis Leigh's figures.

Dr. E. M. DIMOCK said that a family practice had taught him the importance of attention to the organic side of illness. When the doctor had satisfied the patient on this score, the patient was much more amenable to discussion of the emotional factors in his illness. He thought that the domiciliary visit could be of great help to the practitioner, who should be present at the interview. Dr. Dimock thought that most psychiatrists knew far too little about preventive psychiatry, and deplored their tendency, when patients were referred to them, to stir up a lot of mud which, very often, they were unable to settle again.

ASSOCIATION OF CLINICAL PATHOLOGISTS

THIS association met in Exeter on March 26–28. The following are brief summaries of some of the papers.

Effect of Benemid on Uric-acid Excretion

Dr. E. N. ALLOTT said that in the treatment of gout there are two problems: (1) the relief of acute gouty pain, and (2) the prevention of accumulation of uric acid and formation of tophi. 'Benemid,' which was devised to diminish urinary penicillin output by blocking tubular excretion, increases uric-acid output by blocking tubular reabsorption. Normally the increased excretion after benemid may cease after a few days, but in the gouty individual the rise may persist for many weeks. The increased excretion, with prompt fall in blood-uric-acid level has no effect on acute gouty pain. There is, however, some evidence from American experience that prolonged use of benemid may reduce the frequency of gouty attacks. There is no evidence of any permanent renal change after long use of the drug.

Creatine Examinations in Muscle Disorders

Dr. J. N. CUMINGS described creatine metabolic experiments in 67 cases of muscle disorder—myotonia, myasthenia, myopathy, neuronopathy, dermatomyositis, or porphyrinuria. Urinary creatine, creatinine, and guanidoacetic acid were estimated daily, and blood-levels before and after a creatine-tolerance test were also estimated. Normal results were obtained in myotonic patients and in some cases of myasthenia. Grossly diminished tolerance to ingested creatine was found in generalised myopathy, but not in any other disease except in old cases of myotonia with pronounced atrophy. Guanidoacetic acid was unaltered in all conditions except porphyrinuria, in which there was a considerable diminution which, on recovery from the paralysis, changed to a distinct excess.

Idiopathic Renal Acidosis

Dr. W. W. PAYNE remarked that a child with infantile renal acidosis typically presents with a history of normal birth and progress until the age of 4–6 months. Then there develop anorexia, vomiting, and constipation with failure to gain weight. The infant is irritable but hypotonic; there is wasting and dehydration; and fæcal masses are felt in the abdomen. The urine is alkaline; a trace of albumin and a few white blood-cells are present; and often a slight growth of *Bacterium coli* or proteus is obtained. The plasma-chloride is raised above 115 m.eq., and the bicarbonate is lowered below 18 m.eq. With good nursing the dehydration may be corrected, but the other symptoms persist; and a further blood examination after rehydration still shows a lowered bicarbonate but not always a raised chloride. Despite the acidosis the urine is persistently neutral or alkaline. With no treatment there is usually a steady deterioration, but occasionally after a few difficult weeks the infant will recover without treatment. The effect of giving sufficient alkali by mouth to correct the acidosis is striking: the anorexia and vomiting cease, the temper improves, and the weight begins to increase. In 13 out of 35 cases careful radiographic examination of the abdomen showed shadows in the renal areas suggesting calcium deposition. The diagnosis rests on the initial clinical picture, a persistent reduction of the plasma-bicarbonate, and an alkaline urine. No other condition (except forced hyperventilation) will produce an alkaline urine with acidosis. In all uncomplicated cases the final outcome has been complete return to normal after treatment for 2–30 months.

Physiology of Fat Metabolism

Prof. A. C. FRAZER (Birmingham) said that fat absorption in man is most satisfactorily assessed by the daily-fatty-acid-balance method.[1] The intraluminar phase can be directly studied by intubation. With pancreatic-enzyme deficiency intraluminar emulsification does not occur, particulate absorption is impossible, and the chylomicrograph is flat. Intraduodenal injection of finely dispersed emulsion causes a normal chylomicrographic peak,[2] provided that the absorptive prescribing For example, five days' treatment may be completed with 1 million units of crystalline penicillin at a cost of 2*s* 7*d* , whereas five days' treatment with 15 mg of aureomycin per kg body-weight per day will cost about 30*s*

The Bristol Hospitals' booklet gives admirably clear summaries of the preparations, uses, modes of administration, and cost of each drug together with schemes of dosage for adults and children It also gives separate accounts of the local and systemic treatment of burns and of the use of antibiotics to prevent infection in head injuries and in patients in coma The booklet ends with a valuable section on how to take various specimens for the laboratory and a warning on the danger of infection during prolonged intravenous treatment Altogether, it may be warmly commended for its sound common sense

CIRCUMCISION OF THE NEWBORN

CIRCUMCISION is most commonly carried out during the first few months of life, but many pædiatricians delay the operation until soon after the age of 2 years [1] If it is deferred until the child is over 5 years of age, then its protective value against penile cancer seems to be lost [2] Miller and Snyder,[3] who have studied 1480 males circumcised at birth, find that operation at this early age carries no extra risk This is undoubtedly a convenient time for the physician, who "finishes his episiotomy, walks across the hall and circumcises the infant, and is finished with the whole business" The risk of infection is small, for at such a time the infant bears few bacteria, and, with a skilled operator, hæmorrhage is rare Apparently no anæsthetic is needed It might seem that immediate circumcision would enhance the infant's normal early loss of weight, but when these infants left hospital, after an average stay of 5 days, their weight compared well with that of controls, and 98% were gaining weight.

If there is to be circumcision, it is probably best done early, but perhaps operation on the neonate is less likely to become a usual method here than in the U S A , where a higher proportion of women are delivered in hospital

ELEPHANTIASIS NOSTRAS

ELEPHANTIASIS nostras is a most incapacitating condition, known also as Milroy's disease, Meige's disease, and congenital or familial lymphœdema Because of the clinical similarity, the range of lymphatic tissue involved, and the general resemblance of the deformities produced, it has been much confused with the filarial elephantiasis so common in Polynesia, South China, and indeed throughout the tropics, but, whereas in filarial elephantiasis the part played by the adult filaria parasites in the genesis of chronic lymph stasis is pretty well understood, very little is known about the condition of the lymphatic vessels in elephantiasis nostras What is certain is that the disease may be either hereditary or sporadic that it is commonest in females, that it becomes evident about puberty, and that it is extremely chronic and always permanent The swelling usually affects the lower limbs and it is usually circumscribed, in such a way that sometimes the foot escapes—a peculiarity not seen in the filarial disease The œdema gradually subsides to some extent at night-time The orderly progress of the elephantiasis is interspersed by febrile periods, with lymphangitis causing an increase in the swelling As a rule sepsis is a serious complication, and deaths from cardiac failure are not uncommon

Prof *Aldo Castellani*[4] now describes anew this condition as he has observed it in this country and in Portugal He lays emphasis upon the attacks of lymphangitis with high fever and red erysipelas like patches on the skin In these attacks the inguinal glands are generally enlarged and painful, and the skin, which is at first smooth, becomes raised in bosses to form the verrucose variety (elephantiasis nostras verrucosa) Castellani thinks that after some years the bouts of fever cease altogether, and it should perhaps be noted that other observers do not all agree that febrile attacks and lymphangitis are essential features of the condition According to Castellani the scrotum may be affected, and also occasionally the face and lips On symptoms and signs alone, it is, as he says, impossible to differentiate between elephantiasis nostras and filarial elephantiasis, but pathological evidence of the latter may be provided by eosinophilia and sometimes by the presence of microfilariæ in the blood, while in doubtful cases, the intradermal filarial test may be helpful

There seems to be general agreement that the acute phases of elephantiasis nostras are produced by the entrance of streptococci through the skin, or in cracks between the toes as in tinea pedis Castellani, however, believes that the responsible organism is the *Micrococcus* (*Coccobacillus*) *metamyceticus* which he first described in 1933 and 1934, and which was isolated from the inguinal glands in a case of non-tropical elephantiasis When first isolated the organism is a gram negative coccus with definite biochemical reactions, and Castellani holds that a vaccine made from this organism has shown curative value Neither sulphonamides nor penicillin have any effect, but he repeats his opinion that injections of fibrolysin (Merck) in doses of 2–4 ml into the gluteal region three times weekly for two to three months will bring about great improvement, though this does not last The pattern of the pathological changes is described by Castellani as follows first, bacterial invasion of lymphatic vessels and glands, secondly, œdema due to pathological changes caused by the micro-organisms, and, finally, lymphatic hyperplasia affecting the skin and subcutaneous tissues Lymph stasis alone does not suffice to produce elephantiasis, but the lymph, which contains protein in excess, becomes an excellent medium for fibroblasts and micrococci The histological changes of the skin in elephantiasis are great thickening of the dermal and subdermal tissues, close approximation of the nuclei in the malpighian layer, increase in the number of lymph spaces, dilated venules, and thickened arterioles and fibrosis

Although Professor Castellani has made out a good case for his opinions, it must be admitted that much further detailed investigation of the pathology of elephantiasis nostras will be necessary before the exact mode of production of this mysterious lymph stasis can be satisfactorily explained

BRONCHOSCOPY IN TUBERCULOSIS

BRONCHOSCOPY, like oth[illegible] subject to errors of observation and [illegible] chance of error is probably greater with bronchoscopy than with radiography of the chest, since the bronchi are seen by only one observer for a short time and the appearances are not photographically recorded An investigation initiated by the research committee of the British Tuberculosis Association, although not designed for this purpose, suggests that different observers differ considerably in their assessment of bronchoscopic appearances [1]

Six surgeons at six hospitals bronchoscoped a number of patients with pulmonary tuberculosis, each patient was examined by one surgeon only Of altogether 3[illegible] patients 34% were reported to have abnormal broncho[illegible] scopic appearances, but the proportion of abnormal

plugging of the capillaries. Areas of demyelination and neurofibrillar destruction occur in the hæmorrhagic lesions and around many venules, and there is widespread microglial proliferation. Comparison of the lesions with polyarteritis nodosa and postinfectious encephalitis and with experimentally produced hypersensitivity suggests that the disease results from acquired sensitivity of the white matter to a circulating antigen.

Transfusion Errors

Dr. G. H. Tovey (Bristol) described an analysis of 24 transfusion accidents reported from hospitals receiving blood from the South West Regional Transfusion Centre over a three-year period, during which about 40,000 transfusions were administered. The accident-rate was, therefore, 1 per 1660 transfusions; 5 (21%) of the accidents were fatal. In 5 cases (21%) the cause was ABO incompatibility from misgrouping of the recipient and failure or omission of the direct-matching test. Such errors arose mainly because of "short-cuts" in technique. 3 of the accidents (12%) occurred because Rh-negative recipients were incorrectly typed as Rh-positive; in 2 of these cases anti-D was present in the recipient's serum, but D-positive blood appeared to be compatible in 1 case in a capillary matching test, and in the other because the antibody showed a marked prozone effect with albumin-suspended red cells. Failure to detect incompatibility from irregular agglutinins other than anti-D caused 5 of the accidents (21%), the antibodies being anti-Kell, anti-c (2 cases), anti-e, and anti-M. The commonest mistake was the use of a saline-slide technique in direct-matching. 2 accidents, both fatal, resulted from faulty storage. The largest single cause of error, accounting for 9 of the 24 cases, was the transfusion of blood intended for another patient through failure to check carefully the labelling on the blood bottle. Accidents from this cause might be fewer if a coloured group-report were attached to the patient's case-history sheet and each bottle carefully checked against this report before transfusion.

Phthalylsulphacetamide

Dr. W. P. Foster and Dr. K. B. Rogers (Birmingham) said that phthalylsulphacetamide had been described as an ideal sulphonamide for treating intestinal infections and for reducing the bacterial content of the gut before operation. The drug was taken by two ambulant healthy adults in a dosage of 0·3 g. per kg. body-weight per day for 5 days. Within 2 days both had diarrhœa and abdominal discomfort due to excessive bowel movements. By the 5th day both had severe tenesmus and proctitis. The fæcal organisms did not apparently diminish, nor did any organisms disappear during this trial. A carefully conducted blind trial, on student volunteers, produced the same set of unpleasant reactions, which were so severe that the students' work and social activities were interrupted; there was no evidence of any reduction or alteration in their fæcal bacteria. Blood-levels were low in the students, but when the first two subjects took the same course, except for an initial dose of 10 g. instead of 3 g., on the fourth day, there was an average blood-level of 10·9 mg. per 100 ml. A very few cases of *Bact. coli* type 0·111 B4 infantile gastro-enteritis were treated with the drug, without clinical improvement or loss of the organisms. One carrier of *Shigella sonnei* and one of *Salmonella paratyphi-B* were treated without success.

Reviews of Books

Clinical Approach to Fevers

C. J. McSweeney, M.D., F.R.C.P.I., D.P.H., medical superintendent, Fever Hospital, Dublin. London: J. & A. Churchill. 1953. Pp. 146. 10*s.* 6*d.*

Dr. McSweeney records here the course of lectures which he gives to postgraduate students. The presentation is quite different from that of most textbooks on fevers: diseases are not treated systematically, but by considering certain leading symptoms and signs such as sore throat, croup, continued fever, rashes of various kinds, cough, paralysis, and diarrhœa in infancy. There are, in addition, short chapters on the more obvious aspects of virus infections, on general and specific treatment, and on the prevention and control of the common infectious diseases. This is the type of teaching usually given on ward rounds. It is in no way exhaustive or systematic, it takes little account of views other than the author's, and it gives no references or supporting data.

Infectious diseases are notoriously variable from time to time and place to place. Today, when they are often spoken of as if they were dying out, it is interesting to learn that measles in Eire in 1952 was more virulent than at any time within living memory, and that acute infantile gastro-enteritis came like a new disease to Dublin in 1941, causing upwards of 1000 deaths in the city every year during the late war, and remaining severe to this day. In view of this it is disappointing to get no information on the serological variants of *Bacterium coli* as a causal factor in this disease, and no mention of the place of antibiotics in the treatment.

There are a number of surprising statements. Appendicectomy performed during the prodromal stage of fevers is by no means unknown, but Dr. McSweeney has apparently seen "scores of appendicectomised enterics." He still regards sulphanilamide (hardly ever used elsewhere) as the remedy of choice for all hæmolytic streptococcal conditions, including sore throat (in which the evidence of its value is now considered very doubtful). He seems to advocate routine enemas on alternate days for fevers, a practice that has been discarded in most fever hospitals. He is certain that chloramphenicol is a specific remedy for, or outstandingly successful in, virus pneumonia, infective mononucleosis, infective hepatitis, and lymphocytic meningitis. He thinks that *every child under 5 years of age* should be given gamma-globulin within 4 days of exposure to measles (is this possible or even desirable?), that infantile vaccination is unnecessary, and that the original streptomycin used for tuberculous meningitis *invariably* provoked deafness.

There is much that is valuable in this book, but some of the dogma may be misleading.

Ocular Surgery

H. Arruga, M.D. Translated from the Third Spanish Edition by Michael J. Hogan, M.D., and Luis E. Chaparro, M.D. Barcelona: Salvat Editores, S.A. New York: McGraw-Hill. 1952. Pp. 936. 306*s.*

For many years now, ophthalmic surgeons from all over the world have made the pilgrimage to Barcelona, to see the clinic and admire the operative skill of Count Arruga. During the Spanish Civil War, when he had to leave the country, his skill was demonstrated in many lands, and as a result of requests from many quarters he put his surgical experience into a book, now brought up to date in its third Spanish edition.

Though Arruga's name is perhaps more widely known than that of any other ophthalmic surgeon, he has no hospital appointment and only thirteen beds in a private clinic. He believes, like Kocher of Berne, that a few patients thoroughly studied are more instructive to the surgeon than many times that number seen less often. His maxims have always been simplicity, neatness, and a careful study of every patient, and this volume reflects them. Nothing in it is unpractical, nothing unproven in use, nothing fanciful, and the whole is presented with style and finish. In each chapter Arruga first gives his own operations and predilections, then the operations of other leading ophthalmic surgeons, where these differ from his own, and finally, the newest thoughts on the subject culled from journals and society proceedings. As an exposition of modern technique in ophthalmic surgery this book is unequalled and seems likely to remain so.

Developments in Psycho-Analysis

Melanie Klein, Paula Heimann, Susan Isaacs, Joan Riviere. Toronto: Published for the Institute of Psychoanalysis by Clarke, Irwin & Co. London: Hogarth Press. 1952. Pp. 368. 30*s.*

During Freud's lifetime a number of adherents, who developed views which he considered irreconcilable with the basic principles of psycho-analysis, were extruded or withdrew to found schools of their own. This did not happen to Melanie Klein, but her theories are sufficiently divergent, if not schismatic, to have raised vehement questions about her orthodoxy (it is difficult to avoid using religious terms and analogies in this context). Here is a dignified rejoinder to the attacks made upon wrong times, being perhaps at their nadir during critical discussions Playing at home may be as important an advantage in this field as on others

THE SOCIAL ANIMAL

THE neurotic is isolated from the community, to which he cannot adjust Dr Maxwell Jones has tried the effect of giving him a hair of the dog that bit him, by guiding and absorbing him into another social community—that of the hospital Doctors, nurses, and patients provide between them a social unit with a therapeutic power comparable to that of a united family, or of the esprit de corps of other groups

In a new book[1] Dr Maxwell Jones describes three experiments on these lines First he treated soldiers suffering from "effort syndrome," in an emergency hospital during the war Here he mainly developed the educational approach, teaching patients the mental mechanisms of their symptoms , and he found that explanations were readily accepted when they had the weight of group acceptance behind them The second experiment was with "psychodrama," which gave patients the chance to act out their difficulties or to see them re enacted by others These two methods he afterwards modified for the rehabilitation of repatriated prisoners of-war who were having difficulty in readjusting to civilian life His most important and most lasting experiment, however, described in detail, was the establishment of the industrial neurosis unit at Belmont Hospital, Sutton Here he has treated patients of a very different type (though the difference is perhaps not made clear enough to the reader)—to wit, unemployed neurotics of long standing, often considered unemployable by the authorities, patients with "severe character disorders in poor personalities," "some of the most antisocial elements in society" The task was to absorb these social casualties into the transitional community of the unit, to instil some "communal responsibility" into people who had no real place in society before, and to prepare them for their outside rôle after discharge This obviously demands more than average enthusiasm, optimism, energy, and devotion to the idea from all who collaborate in the work, and especially from the nursing staff Probably the most instructive and revolutionary parts of the book are those explaining the nurse's position, the difficulties arising out of the unconventional part she is asked to play in the community of the unit, and the solutions attempted and achieved

Dr Maxwell Jones's colleagues—Dr A A Baker, Dr Thomas Freeman, Dr Julius Merry, Dr B A Pomryn, Mr Joseph Sandler, PH D , and Miss Joy Tuxford—report in separate chapters on their special problems psychotherapy of neurotic inpatients is criticised and justified, techniques of group formations are disentangled, and the special hazards of vocational guidance are described Follow-up study of these patients seems impossible , nevertheless it was tried, and we even find the team in search of a control group of untreated cases They were not able to collect them, but the search disclosed a still more solitary and demoralised layer of unemployable psychiatric patients who refused treatment even in a unit like that at Belmont

Six months after discharge about 100 patients were visited, of whom almost half were working, some of them under sheltered conditions This seems a satisfactory practical result, justifying Dr Maxwell Jones's work It is encouraging to see from his report how his idealism and pioneer spirit have won the support not only of able colleagues, but also of Ministries and other official bodies inside and outside the National Health Service

KERNICTERUS

KERNICTERUS, a peculiar yellow staining of the nuclear masses of the brain in neonates, has long interested clinicians, pathologists, and hæmatologists Originally this condition, which gives rise to a varied clinical picture,[1 2] was believed to be toxic, possibly hepatogenous , later the cause was thought to be sepsis,[3] but this came to be regarded as only a contributory factor[4] When blood-group incompatibility was correlated with icterus gravis, many thought that the problem of kernicterus was solved , indeed, Claireaux[5] suggested that kernicterus was always due to jaundice resulting from hæmolytic disease of the newborn Aidin et al[6], however, described 25 cases of kernicterus in premature infants without any evidence of hæmolytic disease , and their findings have been confirmed in a further 10 cases by Dr Govan and Dr Scott[7] These workers also examined the brains of 3 premature infants who had lived only 48–72 hours and where there ha been a difficult birth , and in these they found histological evidence of brain damage indistinguishable fro that in kernicterus due to hæmolytic disease of th newborn They concluded that anoxia was the primar cause, and deposition of pigment a secondary factor

This explanation, however, does not accord with a the facts Anoxia does not necessarily accompan the birth of a full term erythroblastotic infant , usuall the infant seems perfectly healthy until it become jaundiced Furthermore, the serum-bilirubin of th neonate destined to have kernicterus is usually, thoug not always, much raised Signs of kernicterus com on pari passu with the jaundice, but the disorde does not seem yet to have been diagnosed at the tim of birth It is doubtful if the theory of antigen antibody reaction in the brain as a cause of kernicterus is any longer tenable , in the worst form of hæmolytic disease of the newborn—namely, hydrops fœtalis—histological evidence of brain damage has not hitherto been described

Experimentally bilirubin can cause a brain lesion similar to that of kernicterus,[8] but only if its level is very much higher than that found in erythroblastosis A familial non-hæmolytic jaundice apparently accounted for kernicterus in five members of a family described by Crigler and Najjar[9], and in a letter that appear on a later page of this issue Dr Forrester and Mr Bev suggest that the cause may be pigment derived from abnormal hæmoglobin metabolism Gerrard[2] concluded that hypoglycæmia was not the cause, and he suggested that neither anoxia nor liver damage, but some primary biochemical dysfunction, such as hexokinase inhibition, might prove the underlying factor Dr Saunders[10] has suggested that the cause may be the withdrawal of an inhibiting substance derived from the placenta

Clearly our knowledge of kernicterus is very far from complete It seems, however, that the kernicterus in erythroblastosis and in jaundiced—and non jaundiced—premature infants should be considered together although the manifestations differ somewhat[11] It seems, too, that replacement transfusion will reduce the risk of kernicterus in infants with hæmolytic disease of the newborn , and early induction of labour where there is any likelihood of hæmolytic disease in the infant should be avoided

THE LANCET

LONDON: SATURDAY, APRIL 25, 1953

Bacteriophage

In July, 1952, the first international congress to be devoted entirely to bacteriophages was held at Royaumont; and the proceedings have been published in the *Annales de l'Institut Pasteur*.[1] At this meeting American workers dealt particularly with methods of phage reproduction, while French workers were concerned more with lysogenicity.

Phage multiplication has been intensively studied with the coliphage T_2; and this work has been aided by the development of electro-microscopic techniques,[2] which have revealed that the head of T_2 phage is hexagonal in shape and is composed of a protein shell filled with desoxyribonucleic acid (D.N.A.). Anderson et al.[2] suggest that the tail seen in these phages is hollow and attaches the head of the phage to the host-cell. By osmotic shock the D.N.A. has been removed from the head, leaving the protein skeleton behind. Primary attachment of the tailed phages seems to be by means of the tail, probably by electrostatic attraction[3]; this primary attachment, which is reversible, appears to be the step inhibited by antisera. Hershey and Chase[4] have shown that the subsequent irreversible change leading to infection is due to the passage of D.N.A. into the host. Most of the phage protein remains outside the cell and appears in a form similar to the skeletons seen by Anderson and his colleagues.[2] Thus the protein fraction appears to act as a syringe which injects the phage D.N.A. into the host-cell. Possibly there is a similar type of union between human viruses and their host-cells; but it would be unwise to suggest close analogies between phage and human viruses.

Once inside the cell the reproduction and the genetic pattern of the phage are apparently controlled by the D.N.A. By means of radioactive isotopes several investigators have found that, while up to 30% of the infecting particle's nucleic acid is transferred to its progeny, little or no protein is similarly transferred.[5] [6] It is noteworthy that Wyatt and Cohen[7] have shown that the phage D.N.A. is chemically distinct from that of its host, while the work of Knight[8] suggests that, in animal viruses at least, the protein pattern is in part a reflection of the host species. This might be expected, since it appears that phage protein is synthesised partly from the metabolic pool in the bacterial cell.

Levinthal and Fisher[9] have observed what they believe to be incomplete virus particles in cells that were prematurely lysed; and De Mars et al.,[10] making use of the observation by Foster[11] that proflavine prevented the production of complete phage but did not prevent cellular lysis, produced large numbers of these incomplete particles and subjected them to electron-microscopic study. The morphological similarity between these incomplete phage particles and the empty heads of the phage particles produced by Anderson[2] by means of osmotic shock is remarkable. These observations suggest that there must be two processes of intracellular multiplication of phage—one leading to the production of the protein shell, and the other to the replication of phage D.N.A. Dounce[12] has lately suggested that D.N.A. may not only be responsible for self-replication but may also form a template for protein synthesis.

The increasing use of phage for the study of genetic problems is reflected by the number of papers on phage in the recent Cold Spring Harbor symposium[13]; and it seems that, because of the ease with which it is manipulated and the rapidity of its multiplication, it may become as important a tool as drosophila in the study of genetic problems. Since the initial observation on phage mating by Delbruck and Bailey[14] a mass of data has been accumulated. To this Adams[15] has added information on heat-resistant phage mutants, and Luria and Human[16] on host-induced mutants. On the technical side the observations of Bresch[17] on the use of dyes to differentiate plaque-type mutants may prove very useful. Unfortunately all these observations are unlikely to be fully explained until the exact mechanism of phage multiplication is fully elucidated. Meanwhile, however, Visconti[18] has put forward a new theory of phage genetics that covers most of the observed facts.

As regards lysogenicity Bertani[19] has observed that mutual exclusion, which is a feature of lytic phages, also occurs with the prophage forms; and he believes that his results can be most readily explained by assuming that prophages form an integral part of the genetic structure of the host-cell and are transmitted at each cell division. Wollman[20] also believes that the prophages are genetically linked; but he suggests that prophage may be a form of cytoplasmic inheritance. In this connection it should be borne in mind that Zinder and Lederberg[21] have transmitted genetic characters from one cell to another by means of bacteriophages.

In considering work on phages it is well to remember that these organisms are probably of much greater value for the study of individual problems of virus multiplication and genetics than as models on which to base generalisations about the behaviour of viruses as a class.

"Natural Childbirth"

There are two ways of investigating attitudes—by tabulating the answers of thousands of people to a few questions, or by making detailed inquiries into the views of a few. By this second method Freedman et al.[22] at Yale, have found that the recent memory of twenty mothers for the events of labour was much the same as that of their attendants;

capacities In the absence of a spirometer a useful indication was the amount the patient could count in one breath

When the patient was in the respirator the aim was to give as normal a respiration as possible, and useful figures to remember were a negative pressure of 15 mm H_2O and a rate of 15 per minute The rate must, however, be modified according to the age of the patient and the degree of pyrexia

Necropsy in these cases nearly always showed a collapse of the lowermost parts, and emphysema or frothy œdema of the uppermost parts, of the lung Changes of posture were therefore very desirable If atelectasis occurred the patient should be put in the prone head-down position and positive pressure used Positive pressure was not uncomfortable provided that the negative pressure was correspondingly reduced to give the same total difference, it was useful in promoting cough, in helping to expel secretion, and in aiding venous return to the heart During the acute phase it was frequently necessary to use a resuscitator while the cabinet was open for nursing

Recording Muscle-power

Mr Donal Brooks said that by 1917 *Lovett*, at Harvard, had devised a system of grading muscle-power which differed only in detail from that proposed by the Medical Research Council in 1943 The M R C grading had many advantages it was simple, it required no apparatus or assistance and it had criteria that were reasonably clear cut, it was surprisingly accurate He thought that its widespread adoption by all concerned with poliomyelitis would prove most valuable Mechanical methods of testing, such as the spring-balance and the strain gauge dynamometer, had little advantage, since the high degree of accuracy required made them exacting to use, and only revealed the "scatter" of variation *normally absorbed* by the "elasticity" of the M R C grading They might perhaps be used for comparing the results of different treatments, but any significant recovery of voluntary power should be readily discernible by the simpler methods

Mr Brooks showed a muscle chart devised for use in poliomyelitis, the muscles were grouped according to their function and not according to their nerve-supply, and in addition there was space for recording the power of a particular movement—e g, flexion of the elbow—so that useful trick movement could receive the recognition it deserved

Resistance to Stretch

Mr George Mitchell showed a film on muscle spasm in support of his contention that painful resistance to stretch of the muscles in poliomyelitis is mainly due to root traction

---

SYMPOSIUM ON HUMAN PERFORMANCE

Human performance—one's own or somebody else's—is of interest to practically everyone In one respect, therefore, those who have something to say about it are batting on a safe wicket On the other hand, in so vast a field one must either say little about much or much about little On the whole, the Ergonomics Research Society's symposium at Oxford on April 13-16 tended to deal with particular findings techniques and apparatus, fundamental scientific questions would have been out of place in a gathering of physiologists psychologists, work study engineers, and industrial consultants

The proper function of meetings is catalytic and facilitatory rather than informative, and this "convention" undoubtedly fulfilled its purpose In this connection Prof W E Le Gros Clark F R S, spoke of the valuable stimulus to a university department from contact with applied work, and also the need for the "applied worker" (in this term usage prevails over grammar) to be allowed to give perhaps half his time to fundamental questions

POSTURE

Sir Charles Lovatt Evans, F R S, *in the opening* session, expressed a similar viewpoint in reminding the audience that all science is one He went on to give a brief conspectus of the history of muscle physiology His comment on "so called neuritis" as being probably due to incorrect posture may be associated with the observations, later in the meeting, by Miss Gerda Seiderlin (Copenhagen) on the treatment of aches and pains by muscular re education She insisted that one must go and watch the patient at work (or sometimes at play) Only thus can one detect the habit of posture or movement that is responsible and perceive how to alter it Treatment by rest and by training other muscles does not prevent the patient relapsing into his old habit at work—because, of course, he knows no other He must, in Miss Seiderlin's view, be trained in a better manner of working The principle is not new, and is often impracticable, like so much of common sense, but it deserves to be stated again and again for, like our patients, we are creatures of habit

ENERGETICS

M J Karvonen (Helsinki) recounted some observations on competitors in Finnish lumberjacks' competitions, the finalists are the élite of some 200,000 worker Those who do best are long-bodied and short legged, and—to avoid the jargon-word "correlation"—the bigger they are the better Apparently they do not have to perform those feats of agility that we associate with the Canadian lumberjack "clearing the log jam" Over a third of both the high calorie intake (5460) and the water (4200 g) was consumed at the main meal after work (Metric-Imperial disputants may note the use of grammes as fluid measure)

E H Christensen (Stockholm) argued that the pulse rate is a valuable indication of the physiological load in as much as it signals the stress due, for example, to a hot environment such as a steelworks J G Durnin and his co-workers concluded from their observations on miners in Scotland that this work was, on the whole only "moderately heavy" (i e, 1–1 5 litres of oxygen consumed per minute)

INFORMATION THEORY

W D Garvey (Washington) deduced, from experiments on the coding of stimuli and responses in certain tasks, that it was preferable to arrange that the stimulus response relations could be grasped in terms of spatial rather than verbal dimensions Qualitatively, it is obvious that having to perform some verbal operation such as counting in order to decide on the correct response is a slow business, the importance of the result lies rather in their quantitative aspects E R Crossman presented evidence supporting and extending the now fairly well established law of proportionality between time and reduction of entropy in tasks involving choice (Entropy is a mathematical measure of uncertainty about or disorder in, the material, formally similar to the entropy of physics) The essential feature of the approach is the measurement of "selective power"—i e rate of doing selective work—which is a general criterion of psychological performance, just as horse power (rate of doing physical work) is a general criterion of prime movers However as W E Hick emphasised each can act only as an aid to thought and an indication of fundamental limits Specific supplementary criteria will always be needed for particular cases thrombin; and (3) formation of fibrin. Recent research has tried to analyse these fundamental reactions, especially the first one; and a series of papers from Macfarlane and Biggs and their colleagues at Oxford shows how this can be done, and how ideas on the function of the various factors have been reorientated.

In these experiments the clotting-time of a fibrinogen solution was used as a means of testing the various reactions; and Macfarlane and Biggs[35] used it first to study thrombin generation. A standard commercial preparation of thrombin was diluted and added to the fibrinogen solution, and the clotting-times were recorded: the clotting-time was inversely proportional to the thrombin present. Some fresh venous blood was then put into a glass tube, and small samples were withdrawn at regular intervals until after the blood had clotted. The samples were added to a fibrinogen test solution, and from the clotting-times of the test solution the rate of thrombin generation could be studied. There was a latent period of 2–4 minutes before any thrombin appeared; thrombin generation then reached a peak about 7 minutes after the blood had been drawn, and ceased completely after about 14 minutes. This pattern suggests that an intrinsic thromboplastin is generated suddenly as a result of a slow reaction initiated by surface contact. When thromboplastin—in the form of dried brain—was added to the blood, the latent period was abolished, but the rate of thrombin generation was unchanged. The amount of thrombin formed was proportional to the number of platelets; when these were few—below 20,000 per c.mm.—thrombin formation was much diminished, but the latent period was the same. The latent period was found to depend on the presence of antihæmophilic globulin—the congenital absence of which produces clinical hæmophilia. This finding was put to practical use by Pitney and Dacie,[36] who used citrated plasma, which was recalcified and then used as a means of following thrombin generation in the fibrinogen test solution. They obtained similar thrombin-generation curves, except that with normal plasma the latent period before thrombin appeared lasted for from a few seconds up to 90 seconds. With hæmophilic plasma the latent period in 8 cases was from $2\frac{1}{2}$ to $5\frac{1}{2}$ minutes, and the whole pattern of thrombin generation was grossly distorted. By studying the changes that treatment produced in the latent period and in the thrombin generation curves, they were able to assess the effectiveness of treatment. They found that a transfusion of 600 ml. of 4-hour-old plasma failed to correct the abnormalities completely, even though the whole-blood clotting-time was restored to normal. Similarly, it was difficult to correct the defects with fibrinogen fraction containing antihæmophilic globulin. Using this technique, Pitney and Dacey found that antihæmophilic globulin did not deteriorate significantly in blood stored at 4°C for 1 day, but in 10 days the activity was reduced to 50%.

Biggs and Douglas[37] have used a similar technique in an attempt to make accurate estimates of the prothrombin content of blood. It is now agreed that Quick's one-stage "prothrombin-time" does not measure prothrombin alone; the results are influenced by "accelerator factors," known as factor v and factor vii. Factor v (labile factor, plasma accelerator globulin) is a protein found in the globulin fraction of *plasma*; and it is not adsorbed by inorganic precipitates such as aluminium hydroxide. Congenital deficiency of factor v is known, and deficiency can develop in liver disease or in infection. Factor vii[38] is a protein in the globulin fraction of *serum*; and it is adsorbed by alumina. Its importance lies in the fact that anticoagulants such as dicoumarol and 'Tromexan' (ethyl biscoumacetate) are now believed to act, not by depressing prothrombin, but by depressing factor vii; and further evidence supporting this view is given by Professor Hunter and Dr. Tudhope on an earlier page of this issue. Plasma adsorbed with alumina contains factor v, but not prothrombin or factor vii; on the other hand, normal serum after complete clotting contains little factor v or prothrombin, but does contain factor vii. Consequently the one-stage clotting-time of a plasma deficient in factor v will be shortened by the addition of alumina-adsorbed plasma. If it is deficient in factor vii, the addition of normal serum will have this effect but alumina-adsorbed plasma will not; and plasma deficient in prothrombin will still have a prolonged clotting-time with both reagents. There is no doubt that in many of the cases reported as idiopathic or congenital hypoprothrombinæmia the accelerator factors were also involved. Biggs and Douglas were fortunate in being able to study a case of pure prothrombin deficiency in a man of 26 who had had hæmorrhagic symptoms for 15 months. They adapted the thrombin-generation test to the estimation of prothrombin by carrying out the usual Quick one-stage plasma clotting-time and then following the generation of thrombin in the clotting mixture up to and after the time when the clot formed. They plotted the results as a graph of thrombin units against time, and showed that the prothrombin content of the blood could be estimated by determining the area enclosed by this graph. Their patient proved to have only 11% of normal prothrombin activity, but factors v and vii were not deficient. By this technique, a patient under effective anticoagulant control with tromexan—as judged by the Quick "prothrombin time"—was found to have 68% of normal prothrombin activity. This emphasises the fact that, as Biggs and Douglas point out, this method of prothrombin estimation is no use in the control of anticoagulants. The usual one-stage clotting test, which measures factor-vii deficiency, is still the correct one to use, and Hunter and Tudhope's results confirm that it is suitable for routine use.

The next step was taken in an effort to find out more about the defect in hæmophilia. It is now known that in hæmophilia a factor essential for the development of thromboplastin is absent. Quick called this factor "thromboplastinogen," and it is also known as antihæmophilic globulin. Biggs and Douglas[39] therefore set out to reinvestigate the formation of thromboplastin. While doing so they and their colleagues[40] investigated a disease to which Poole[41]

East and Central Africa the fever is commonly carried by the tick, *Ornithodorous moubata,* but on this occasion in the Gold Coast it was conclusively proved to be transmitted by the body-louse The acting director of medical research, Alexander Ingram, kept three or four lice, which I gave him from one of my many relapsing-fever patients, in a watch-glass fixed on to his wrist by adhesive plaster In his sleep the irritation must have been so intense that he scratched a louse, or its infected excreta, into his skin He went down with an alarming attack of fever, and his blood smears swarmed with *Spirochæta recurrentis* Fortunately, as is usual with this disease, he reacted rapidly to intravenous injections of neoarsphenamine In my experience (limited, it is true, to treating a large number of Zaberrima tribesmen) relapses were unusual after doses of 0 3, 0 45, and 0 6 g on the first, fourth, and seventh day of treatment, provided one was careful to counteract the collapse which often accompanied the startling fall in temperature from, say, 105° to 96°F within twenty-four hours

In 1924 bubonic plague broke out in West Africa Many cases had been reported earlier from the French Senegal, where Dakar is one of the chief ports for the export of ground-nuts—and nuts attract rats It was never definitely established how the infection came to the Gold Coast, but it may have come by car A car belonging to the newly appointed town engineer of Kumasi, the capital of Ashanti, had been mistakenly carried on (like the lady bound for Birmingham) to Lagos in Nigeria Here, the ship had been berthed alongside the wharf. Rat guards on mooring-ropes are notoriously inefficient, and a plague infected rat or two may have got aboard On the return journey the car was disembarked in the Gold Coast and sent up by rail to Kumasi Its performance was not all that had been expected, and on investigation a rat's nest was found under the bonnet Some of the material from which it had been made obviously came from a ship The first people to go down with plague in Kumasi were labourers employed in unloading goods trains at the siding where the car had arrived

Most patients had the bubonic type of plague which itself carried a high enough mortality, but there were also a number with the pneumonic type, which was almost always fatal within forty eight hours of onset I had only one patient who recovered from a plague pneumonia He had large axillary and inguinal buboes, and a typical pneumonia with *Pasteurella pestis* in his bright bloodstained sputum By all accounts, he should have died Instead, I lost my senior male nurse, who was usually very careful with his mask, gum boots, and so on

As in many other plague areas, the black rat (*Rattus rattus*) was the main carrier, although the brown rat (*Rattus norvegicus*) and the pouched rat (*Cricetomys gambianus*) were minor carriers *Xenopsylla cheopis* and *X astia* were the fleas usually found on these rats but, curiously enough, the human plague victims were usually lousy and not flea infested

Malaya

In 1930, I left West Africa and spent the next year or so as chief health officer in the Federated Malay States Here malaria was one of the main causes of ill health On the coast the malarial parasite was carried by *A sundaicus* or *A ludlowi* which can breed in brackish water Further inland, *A umbrosus,* which prefers the shaded water of the plains, was the vector *A maculatus* was the chief enemy in the foothills and along the mountain range, where it bred in fresh clear streams, or in drains or seepages of clean water, exposed to sunlight Recalling the ubiquitous breeding of *A gambiæ* and *A funestus* in West Africa, I should say that these mosquitoes were a slightly greater menace in Africa than, say, *A maculatus* was in Malaya in those days

I came across two types of typhus in the early '30s —the louse borne variety, often in Bengali cowmen, and the scrub variety, carried by the Kedani mite (*Trombicula akamushi*), affecting especially labourers working on red-palm nut estates where rats abound The mite is carried by the rat and gets on the legs of those walking through grass

Two interesting conditions seen in Malaya are probably forms of psychomotor hysteria In latah, the sufferer feels obliged to copy any and every action of his companions For example, a boat is being poled up a river and it is clear that one of the crew is going to have an attack An unkind companion attracts his attention, and pretends to dive in The victim promptly plunges into the water—a cruel trick, for the rivers are usually very shallow and muddy

The second form has been made familiar by the expression "running amok"

One sultry evening several years ago, a Straits steamship, the S S *Klang,* was about to leave Singapore on what was to be the last trip of its master before he retired after many years of honourable service A Malay passenger, who before coming aboard had met with a series of annoyances (pigs had got into his garden, his wife had "made eyes" at his neighbour, and so on), had made a bargain with one of the crew earlier in the day to hire the man's bunk for the voyage When he went below to take possession of it, he found already occupied by another passenger who had given a bigger bribe and who refused to be dislodged The worried and disappointed Malay whipped out his parang and slashed his unfortunate fellow passenger He then went in search of the deck hand who had tricked him In a moment there was an uproar, and crew and passengers flew in all directions, down companion ways and up the rigging, but twelve were not quick enough and were cut down

Hearing the noise, the captain and chief officer went below to investigate As the captain went towards the Malay to persuade him to give up his weapon, he was slashed in the stomach The chief officer then threw a marline spike at the Malay, knocking him into the scuppers When the police came aboard the captain lay dying, the chief engineer and eleven others were dead, and the Malay lay wounded in the head

Hong-Kong

In the early spring of 1938 I landed in Hong Kong The Japanese had attacked China in 1931 and had seized the five Northern Provinces in July, 1937 Refugees were seeking sanctuary in Hong Kong in considerable numbers I had been asked to go there as director of medical services by the then Governor, under whom I had served in West Africa

Within seven months of my arrival in Hong Kong the Japanese had ranged south, landed in Bias Bay, and captured Canton Their flags were soon flying on the hills bordering the Colony's Leased Territories, and they remained there until the morning of Dec 8, 1941, when they attacked us After eighteen days' bombing and shelling they captured Hong Kong

The three years before the attack were spent in organising civil medical defence and in dealing with the difficulties caused by the influx of refugees from China In 1937, the population of the Colony was rather over 800,000, by 1940 it had risen to about 1,750,000 By the time the Japanese attacked, the population had been reduced by repatriations to just over 1,600,000 During the occupation it fell by forcible repatriation, executions, and deaths from starvation to less than 600,000 at the time of the liberation on Aug 31, 1945

When I arrived in 1938 the wards of the Chinese hospitals were full of sick and injured two or more to a bed, many more were on the floor between beds and even under beds, and verandahs and corridors were crowded It took some time to bring order and cleanliness out of this chaos Step by step, the Chinese director view. It is now very clear that the autonomic nervous system, as we understand it, has a very minor rôle in the maintenance of resting blood-pressure, and that this system is not disordered in essential hypertension. Furthermore any benefit from sympathectomy is not closely related to the extent of the sympathetic-nerve section. Although sympathectomy in a rather capricious way sometimes benefits hypertension, there is no agreed explanation of the mechanism.

Blood-pressure in hypertension can be consistently and substantially reduced by a diet low in calories and with an extremely small sodium content (less than 100 m.eq. per day)—for example, the Kempner rice/fruit diet. Unfortunately, indefinite adherence to such a diet is only possible for obsessional patients with a substantial masochistic trait. The prevention of sodium absorption from the alimentary tract by ion-exchange resins, though practicable in the metabolic ward with extensive and skilled biochemical control, is very difficult—indeed dangerous—in routine practice. Many drugs will lower blood-pressure in hypertension. Prominent among these are the polymethylene bis-trimethyl-ammonium compounds, discovered by Paton and Zaimis,[49] which block autonomic ganglia. Hexamethonium bromide is the most popular of this group, and a great deal is now known of its potentialities. Administration by mouth is of little value, since absorption varies and tolerance is rapidly acquired. Injection treatment, however, reduces blood-pressure satisfactorily in a large proportion of hypertensive patients. Unfortunately, they may have very uncomfortable toxic side-effects, such as postural hypotension and gastro-intestinal disturbances. Thus, the use of this drug calls for attentive medical care and intelligent coöperation by the patient, and its use is advisable in only a small proportion of patients; its principal place is in the treatment of the malignant phase. 'Apresoline' (1-hydrazinophthalazine), a comparative newcomer to this field,[50 51] is believed to act by opposing humoral pressor substances such as hypertensin. Riven et al.[50] report results of treatment in 65 hypertensive patients. In the majority the pressure was substantially lowered. They conclude that apresoline is effective in the short-term control of blood-pressure in certain cases of essential hypertension and malignant hypertension, but is useless in renal hypertension. Fully half the patients had unpleasant side-effects, and 10 of the 65 had to discontinue taking the substance. As regards the drug control of hypertension, there is still no agent substantially superior to hexamethonium, with all its limitations.

The latest therapeutic essay consists in subtotal adrenalectomy.[52] From the purely theoretical aspect this has much to commend it; for a large body of physiological data points to the homeostatic rôle of the adrenal cortex in maintaining blood-pressure. Indeed, as physiological knowledge stands at present, adrenalectomy has a far more solid rationale than sympathectomy. Nevertheless, while bilateral adrenalectomy may lead to a better understanding of the origin of hypertension, it is only practicable when cortisone is available to tide the patient over any crisis of hypoadrenalism. Perhaps the hazards of thyroidectomy seemed no less formidable to the clinicians of a previous generation.

Although the immediate prospects of helping the hypertensive patient are poor, the future is full of promise. Meanwhile, the kindest thing to do when one discovers a patient with hypertension but no symptoms is to keep the information to oneself.

GOOD SENSE ABOUT ANTIBIOTICS

THE United Bristol Hospitals have recently produced an excellent booklet of fourteen pages[1] which offers a practical guide to the use of sulphonamides and antibiotics. Members of the teaching staff of the University of Bristol contributed the information, which was arranged to meet the needs of housemen; but the publication contains much of value to a wider audience. Its declared object is to explain the general principles and give enough detailed information to enable a rational plan of treatment to be formulated for individual patients, and to prevent the disappointments and even dangers of starting a line of treatment which has little prospect of success and may interfere with correct treatment later on.

If harm will not result from delay, chemotherapy should await identification of the causal organism and determination of its sensitivity; if necessary the bacteriologist should be brought into consultation. If the patient's condition is so serious that instant treatment is essential, specimens should be taken for laboratory examination before any drug is given, and the essentials of the case should be reported to the person who will examine the specimens. Adequate laboratory examination is a necessary part of properly planned treatment, and clinicians who keep up a close personal relation with the bacteriologist know how much he can contribute if he is given enough information to direct his work to the situation in each case. Conversely, those who treat the laboratory as an automatic machine are likely to find that its response is seriously impaired by their own defective understanding of its methods and functions.

The causal organism and its sensitivity do not alone determine which antibiotic should be used; for there are also questions of toxicity, development of resistance, ease of administration, and cost. Streptomycin, the most toxic of the antibiotics in common use, may cause deafness and vestibular disturbance. For this reason, and because it quickly induces resistance among organisms, it should not be chosen casually if a less toxic drug will serve. In tuberculosis, of course, streptomycin has a special place. Sulphonamides should not be forgotten. Against many infections they are extremely effective, and the newer preparations show very little toxicity if administered with enough fluid to prevent crystalluria. We have still relatively little experience of chloramphenicol, aureomycin, and terramycin, and for that reason have not reached stable perspectives about these drugs. Clearly chloramphenicol has a special place in the treatment of typhoid and rickettsial infections; but it is too early to evaluate fully the risk of aplastic anæmia which is associated with chloramphenicol,[2] and of moniliasis,[3] intestinal dysfunction,[4] and untoward effects on the liver which have all been reported as complications during treatment with the newer antibiotics. Despite occasional reports of sensitivity to penicillin this drug remains the safest of all.

Organisms originally sensitive to a drug may quickly become resistant during treatment; but group-A hæmolytic streptococci and pneumococci do not become resistant to penicillin, whereas staphylococci, especially those found in hospitals, may be resistant to penicillin even before treatment is begun. Gram-negative bacilli are generally insensitive to penicillin. Penicillin and streptomycin must be injected, whereas the other substances are normally given by mouth; chloramphenicol is not suitable for intravenous, intramuscular, or intrathecal injection. Penicillin and the sulphonamides are substantially cheaper than the other antibiotics, and this should be remembered in view of the high cost of private enterprise must play a progressively bigger part and proportionately relieve the Exchequer

Turning to the N H S , he said that here the problems were so complex that the Government had sought the assistance of a committee He failed to see why it should be called political cowardice for those who intended to maintain the health service to have it impartially examined, so that those who paid for it, whether political or non-political persons, should get value for money spent

In the course of the debate Mr **Ralph Assheton** declared that in two budgets the Chancellor had proved that the Tories were not out to destroy the Welfare State What they wanted was to make it solvent, and to earn enough money to pay for it and continue the policy of letting the strong help the weak He submitted that we must find ways of doing that, so that the more capable citizens were not crippled in order to benefit those who were less worthy or less industrious

The review of the health service was timely He felt that more financial responsibility might be placed on the hospital boards and that there should be less effort spent in the minute control of expenditure from Whitehall

LESS ON LESS

Mr **Arthur Blenkinsop** pointed out that there was a slight reduction of £20 million in the health service estimates compared with last year, but he agreed that this was largely accounted for by the exceptional expenditure last year on back payments under the Danckwerts award In practice that meant that about the same amount of money was available for the health service as last year It was, however, misleading for the Chancellor to suggest as he did that further increased expenditure was to be made possible The increase of £18 million was only an increase over the estimates of last year and not over the actual expenditure In fact the amount of money available would be about the same

This meant, Mr Blenkinsop declared, that in terms of service much less would be provided for the same money, because £6½–7 million extra would be needed to cover wage and salary advances to hospital staff which had been negotiated during the last twelve months That sum would have to be taken from the money available to the hospital part of the service There would also be a considerable increase in hospital food bills All these increases, he affirmed, could only result in reduced quality of service, unless we had an increase in the now quite artificial ceiling which had been maintained in the N H S for the past four years

In examining the estimates of the health service he found astonishing facts about the reductions secured over last year There was, for instance, a considerable drop in the medical staff, particularly in teaching hospitals This might be partly due to some of the senior registrars going out of the service Despite what had been said about the need for reduction of administrative costs, the estimates showed considerable extra provision for the administrative staff of the N H S Mr **Roland Jennings** interjected that Mr Blenkinsop seemed to be making out a good case for the proposed inquiry into the service But with this Mr **Blenkinsop** did not agree The facts were well known, and no further inquiry was needed It was for the House of Commons to tackle the matter

Continuing his analysis of the estimates he pointed out that for the maintenance of buildings and plant only £8½ million were provided compared with the wholly inadequate £9½ million provided last year All over the country people responsible for the maintenance of hospital buildings were seriously perturbed If we did not carry out maintenance work—such as painting, repairs of plant, heating appliances, and boilers—we should be faced with heavier bills in the future unless we were prepared to close whole sections of our hospitals

Mr **Aneurin Bevan** said that he would support an investigation into the structure of the N H S but asked why the Minister of Health had not been doing it He had plenty of machinery why had he not used it? Mr Bevan alleged that the Conservatives were seeking to undermine the structure of the service, by creating the impression that its finances were extravagant and out of hand, and that some means must be found to bring them under control But in fact, he asserted, if all the charges on the N H S were abolished, and if the whole of the Danckwerts award was set against the expenditure made on the service, the expenditure in 1952–53 would still be a smaller proportion of the national income than it was in 1950 If the Chancellor had any reliefs to offer, had not the aged and sick first claim ?

VALUE FOR MONEY

Mr **Butler**, in his reply to the debate, quoted President Eisenhower's words "The monuments to this new kind of war should be roads and schools hospitals and homes, food and health" That this was precisely the aim also of our Government was, he suggested, borne out by the estimates for education (up by £26 8 million), homes (up by £8 9 million), assistance (up by £24 4 million) He reminded his listeners that the old age pensions had been raised by this Government, and that since October, 1951, assistance scales had been increased by 16 % for a single person and 18 % for a married couple, while the index of retail prices had risen only by 7½ % He admitted that the cost of food in the same period had risen by 15 %, but that was still not as great as the rise in the assistance scales

Turning to the health service he recalled Mr Bevan's comparison, in his resignation speech, of the fate of the health service under the Tories to that of Lavinia, the heroine of *Titus Andronicus* "The Health Service will be like Lavinia—all the limbs cut off and eventually her tongue cut out, too" Mr **Bevan** interposed that taking discussion of the N H S out of the House of Commons and handing it over to a committee was the modern form of taking out the tongue But Mr **Butler** asserted that the committee was appointed to get value for money The committee had been given no total of expenditure to which they had to work but an open remit to report on the health service Mr **Marquand** asked why, then, the terms of reference said they must avoid a rising charge Mr **Butler** went on to say that members of the committee had been chosen with a particular regard to avoid politics If this could be called removing a child which Mr Bevan regarded as his own from his care, Mr Butler believed that the public in general would be delighted to see this particular child boarded out with a respectable committee

Compensation for Partially Disabled Workers

In the House of Commons on April 17, Mr T W **Jones** drew attention to the inadequate rates of compensation payable to the partially disabled under the Workmen's Compensation Acts In his reply, Mr R H **Turton**, parliamentary secretary to the Ministry of National Insurance, announced that the Minister had proposed a scheme to the National Insurance Advisory Committee to remove existing restrictions which prevented a married man on workmen's compensation from drawing his full sickness benefit In what the Ministry regarded as the hardest cases the new proposals would mean a supplementation of 10s a week in some cases and 15s in others for the totally disabled The committee had approved the suggestion, and draft regulations would be introduced

QUESTION TIME

Nursing Services

Replying in the House of Lords on April 16 to Lord Crook, Lord **Woolton**, Chancellor of the Duchy of Lancaster, said that on Dec 31, 1952 there were 47,673 full time nurses and 8381 part time nurses employed in hospitals in England and Wales (including Ministry of Pensions hospitals and those outside the N H S) There were 30 475 student nurses in training Local health authorities employed 6736 full time trained nurses 11 468 part time trained nurses 7723 full time other nurses (including nursery nurses) and [illegible] part-time other nurses Approximately 1700 nurses were findings reported by the different surgeons ranged from 18 to 85%. Minor abnormalities were recorded in from 3 to 45%, and major changes, such as œdema, granulation, or ulceration, in from 0 to 50%. The surgeon who reported the least abnormals (17 out of 91) found no gross changes in any patient; the one reporting the most abnormals (29 out of 34) found major changes in 50%. The prevalence of clinical and radiographic appearances believed to suggest bronchial lesions varied from 7 to 40% at the different hospitals. There were, therefore, wide differences in both clinical and bronchoscopic diagnoses; but there was no clear relationship between the two. Thus, at one hospital 7% were judged to have clinical evidence of bronchial disease and 50% bronchoscopic evidence, compared with 40% and 33% at another hospital. The groups may not have been comparable—it is impossible to judge from the data in the report—but it seems unlikely that the wide differences in bronchoscopic reports were entirely due to differences in the types of patients examined.

Some time ago we suggested that an apparently normal mucosa at bronchoscopy may not exclude gross bronchial disease.[2] In the British Tuberculosis Association investigation 95 patients had a pneumonectomy or lobectomy, and the bronchus at the point of section was examined microscopically. Of the 95, 56 had been reported to have no bronchoscopic abnormality; in only 2 of these 56 was there no microscopic evidence of tuberculosis, while in 32 (57%) there were epithelioid tubercles or a severe inflammatory reaction with tuberculous granulation tissue, ulceration of the mucosa, and fibrosis. Abnormal bronchoscopic appearances had been reported in 39; no microscopic evidence of bronchial tuberculosis was found in 2 and only minor changes in 10 (25%).

It seems that the bronchoscopic report can sometimes give the physician a very inaccurate indication of the state of the bronchi; for there may be great differences not only between the interpretation by different observers of what they see, but also between their reports and the microscopic appearances.

POSTOPERATIVE METABOLIC CHANGES

An operation, like any other injury, produces a characteristic metabolic disturbance. Twenty years ago Cuthbertson[3] described the brisk katabolic phase which after a few days changes rather abruptly to a less intense but longer period of anabolism. Moore,[4] who has studied the matter intensively, has summarised present knowledge. He believes the early katabolism to be due to adrenal hormones and points out that its cessation is marked by features (diuresis and transient eosinophilia) that are also observed on withdrawal of administered cortisone. It is at this stage, too, that wound healing begins in earnest. Moore finds that it takes about a month to rebuild the protein squandered in the katabolic spree, and another month to restore lost fat. This pattern is of course often disturbed by specific effects of particular diseases or operations.

Is all this metabolic to-do necessary? Apparently not, for if a second operation has to be performed within a few days of the first, the katabolic response is absent and yet recovery may be unimpaired. Moore believes that this response is homœostatic, and that the protein breakdown mobilises amino-acids for wound repair. This seems odd, if repair does not get under way until the katabolic phase is over. A clean operation under anæsthesia is such an artificial circumstance that the body's response may not be optimal. The same response, or something very like it, occurs as part of the general illness of inflammation, and its teleological significance should perhaps be sought there.

CATCHING UP WITH THE CLOCK

There are many physiological diurnal variations; the most familiar is the cycle of sleep and wakefulness, and associated with it are the rhythms of body-temperature, metabolic rate, and heart-rate, the fluctuations in the composition of the blood and in renal function, and many other changes.[1–3] Kleitman, who has been one of the most prominent investigators of these changes, has proposed that diurnal rhythms should be distinguished from periodicity by their persistence when, for example, the cycle of sleep and wakefulness is changed. A worker who is transferred from a day to a night shift has to face not only alterations in the social pattern of his life but physiological stresses caused by the persistence of the diurnal rhythms. The daily variation in body-temperature is the simplest of these rhythms to study, and there are many data[2] which show that the commonest pattern consists in a gradual rise of temperature during the day, reaching a peak about 6 P.M., followed by a fall, which may be more abrupt, the lowest level usually being reached between 2 A.M. and 4 A.M. The difference between the highest and lowest body-temperature is usually 1·5°–2·0°F, but there is considerable individual variation from day to day in the same person, and from subject to subject, as well as in the pattern of the fluctuation. When work is changed from day to night, the usual diurnal rhythm changes only gradually, so at first the night worker will have a peak of body-temperature during sleep and a low temperature during work. A new rhythm is eventually established so that body-temperature rises during the night and falls in the day, but this change may occupy a week or more. Once again there is considerable individual variation in the time taken; some people have rhythms which adapt rapidly and others slowly. This individual variation may partly account for the ease or difficulty with which different people can change their hours of work.

Strughold[4] has lately examined another situation in which the day-night cycle is altered. In long-distance flights the aircraft's passengers must change their watches with bewildering frequency; and the "physiological cycle," adjusted to day and night in, say, London, may be very much out of step when the journey ends in Tokyo thirty-six hours later. Strughold has followed (though not in great detail) the diurnal temperature rhythm before, during, and after flights between London and New York, when there is a time shift of five hours. The body-temperature rhythm is out of phase at first, but within a few days the peak is once more reached in the afternoon, with the lowest readings at night. The time taken for this physiological adjustment is probably very variable, but more observations are needed on this point.

Has the fact that the diurnal rhythms are out of step with the day-night cycles any important effect, or is it only of academic interest? The pattern of sleep is disturbed; and the many other rhythms, which have not yet been fully investigated, are also upset. Kleitman has shown, too, that the curve of efficiency in a number of different tasks follows the body-temperature curve. Accuracy and speed of performance increased as the body-temperature rose, and declined when body-temperature fell. There seems, then, to be a good explanation for the traveller's common complaint of fatigue and lack of efficiency in the days following a long-distance flight. Strughold points out that this is certainly not a serious medical problem, but it has its important aspects. Diplomats who fly long distances to attend international conferences may not be as capable as they would normally be, or they may reach their peak of efficiency at the

Care Organisers at their meeting on March 28, when they discussed housing problems of the tuberculous in London

In an opening paper, Dr KENNETH MARSH observed that most of the child contacts of new cases coming to his clinic were already Mantoux positive, and most adolescent contacts showed evidence of healed primary infection He was concerned about the urgent need to teach patients and their families how to live sensibly to minimise the risk of infecting young contacts He emphasised, too, the danger of perpetuating in the new house the unhygienic habits and circumstances of the rehoused family The need to separate careless elderly infective patients from rehoused young and healthy families raised the problem of how to deal with the tuberculous bachelor or widower who could be such a danger lodging in a home where there were young children Dr Marsh said that it was important to avoid rehousing tuberculous workers too far from their workplaces and to discourage rehoused tuberculous families from the temptation to get into debt in refurnishing their new houses

Dr H D CHALKE, an L C C divisional medical officer, described his "points" system used in awarding selective priority to tuberculous rehousing applicants This was based on standardised criteria, which were, in order of "merit," large families, adolescent contacts, infectious cases, shared bedroom, likelihood of prolonged illness, and a real prospect of benefit by rehousing But, he said, a diagnosis of tuberculosis did not, of itself, give automatic advantage in the competition for new houses

Dr VICTOR FREEMAN, medical officer of health for Islington, pointed out that many other sick and disabled persons, apart from the tuberculous, sought and merited priority in rehousing Of the 750 families rehoused by his borough council last year, 6% had been given priority because of tuberculosis 10% of all Islington's accepted family applicants for rehousing were tuberculous, and these 150 applicants were likely to have to wait a considerable time yet before their turn came

Mr J W R PORTER, of the L C C housing department, said that in the past 63 years the L C C had built some 150,000 dwellings housing 500,000 people At present 180,000 families wanted new houses The council regarded 70,000 of these as "most urgent" all sputum-positive tuberculous applicants were in this category Last year the L C C completed 9000 new houses and 700 of these went to tuberculous families It was clear that some time must elapse before even the "most urgent" could be rehoused 5% of newly built accommodation consisted of one-roomed dwellings intended primarily for elderly persons, 15% were two-roomed (i e, 1 bedroom and 1 living room), 40% three roomed, 30% four-roomed, and 10% five roomed It was proposed in future to reduce the proportion of two roomed and of five roomed dwellings The existence of five varieties of house in effect divided the waiting list into five "queues" and explained occasional apparent anomalies in the rehousing of an elderly or young childless couple, needing only two rooms, before a large family, who might have to wait longer for the completion of a four-bedroomed house Tuberculosis commanded more priority points than any other single factor The tuberculous applicant also got special consideration in the allocation of a house which was near to his work, and not too high up in a block of flats The council's system of priorities resulted in 8% of newly allotted houses in any year going to families in which there was active tuberculosis

In discussion, it was said that the L C C has two hostels for ambulant and homeless men with infectious tuberculosis where full board and lodging was provided at charges assessed on each resident's means Some L C C estates outside London now have a prevalence of up to 35 tuberculous persons per 1000 inhabitants—more than three times London's present prevalence Nevertheless it had been established, that the incidence of new cases of tuberculosis on new estates, both inside and outside London, was only one-third or less of what might have been expected from the high comparative prevalence New cases of tuberculosis were rare in rehoused tuberculous families But we cannot yet say whether this is a result of their brighter homes and their new way of life, or the outcome of the heavy attacks already made upon them by the tubercle bacillus

Smallpox

The total of confirmed cases of smallpox in the outbreak in Lancashire and the West Riding had risen to 25 by noon on April 21 There were 2 new cases in the week beginning April 14, and 1 of them, a man aged 61 in Morley, near Leeds, has died, bringing the total of deaths to 6 This man, a claypit worker fell ill on April 13 A rash appeared three days later, and he was admitted to hospital on April 17 He died the same day of hæmorrhagic smallpox An unvaccinated boy of 16, living in Colne Valley, was admitted to hospital on April 15 after six days' illness, now confirmed as semiconfluent smallpox The total does not include a woman in Bury who was admitted to hospital on April 20 with what is in all probability smallpox There is at present no news of the source of infection in the new cases The illness of the Leeds boy, whose death on April 14 we reported last week, has now been confirmed as smallpox

Outbreaks of Communicable Disease in Hospital

In a circular[1] to hospital authorities the Minister of Health reminds hospitals that it is essential to send prompt information to the local medical officer of health on the occurrence not only of a notifiable disease but also of any unusual outbreak of communicable disease, and to give the M O H every opportunity and help in investigating such outbreaks when he considers this to be necessary The circular mentions instances in which outbreaks of, for example, salmonella food poisoning, encephalomyelitis, diphtheria and infantile gastro enteritis came to the notice of the M O H only after considerable delay and by indirect and fortuitous means Quite apart from the question of actual outbreaks, the Minister recommends hospitals to avail themselves of the help the M O H and his staff can give in maintaining the highest standard of hygiene The Minister also urges all hospitals which have not already done so to consider appointing a committee to deal with the control of infection, as recommended in a memorandum prepared by the Standing Nursing Advisory Committee and issued in 1951 The memorandum suggested that a medical officer should be designated by the hospital authority to exercise executive responsibility for the control of infection in hospital and that the M O H of the district should be a member of the committee

Northern Ireland in 1952

The Registrar-General for Northern Ireland reports that the general death rate, the infant-mortality rate and the death-rate from tuberculosis for 1952 were the lowest ever recorded For the first time since records have been kept no deaths were reported from diphtheria The death rate was 10 8 per 1000 population—a decrease of 2 0 compared with 1951 when the death-rate was exceptionally high owing to the severe epidemic of influenza early in the year The death-rate from tuberculosis continued to fall and now stands at 30 per 100,000 population This rate is approximately one third of that of twenty years ago During the same period the infant-mortality rate fell from 83 per 1000 live births to 39 For the past three years the maternal mortality rate has remained unchanged at 1 1 per 1000 live births (which is the lowest rate ever recorded for Northern Ireland), compared with 5 3 per 1000 births in 1932 The elimination of diphtheria seems to be within sight, for only 4 cases were notified during 1952 In 1942 there were 91 deaths and 1100 cases recorded

SYMPOSIUM ON POLIOMYELITIS

A WELL attended symposium on poliomyelitis was held at the Nuffield Orthopædic Centre, Oxford, on March 12.

Prof. J. TRUETA recalled how poliomyelitis first developed severe epidemic proportions at the end of the last century, starting in Scandinavia and then reaching North America whither it was thought by some to have been carried by immigrants. Before that time only small groups of cases had been reported both in Europe and in North America. The first major North American epidemic was in 1907—two years after Sweden had 1200 cases of poliomyelitis with 145 deaths. By 1912 notification of the disease had been made compulsory in 20 of the United States. In 1916 New York State alone had 13,000 cases with a mortality of 27·2% in New York City. Nothing comparable had yet occurred in this country, which did not have its first epidemics until 1947 and 1950; in each of these years 8000 cases occurred in England and Wales. These two recent epidemics, and the severe epidemic last year in Copenhagen with its high proportion of respiratory and bulbar cases, had made it necessary for those responsible for dealing with the disease to plan now for similar large-scale epidemics before they actually occurred.

Professor Trueta recalled that his predecessor in the Oxford chair of orthopædics—the late G. R. Girdlestone—had been one of the first to plan for the severely paralysed victims of the disease. He hoped that Oxford would continue to be a centre of initiative in the fight against poliomyelitis, and that the Oxford region might perhaps take the lead in planning the establishment of quarantine in poliomyelitis.

Poliomyelitis and the Infectious-disease Hospital

Dr. J. B. M. DAVIES, deputy medical officer of health for Oxford, said that poliomyelitis, particularly in the early stages, was extremely infectious; isolation was therefore essential, and this was most easily carried out in infectious-disease hospitals. The present policy of limiting isolation to three weeks was only a "half-loaf" policy, since the excretion of virus in the stools might continue for up to ten weeks; but it more than covered the most dangerous period of a week to ten days when the virus was present in the nasopharynx. Not all infectious-disease hospitals, however, were suitable for the admission of poliomyelitis patients; and certain suitable hospitals should be selected for the admission of these patients. The main objection to this was the distance that patients might have to travel. How far the patient travelled was, however, less important than when he travelled; every effort should be made to obtain admission of these patients when the diagnosis was presumptive rather than in the late stage of spreading paralysis. No practitioner should feel that he ought to await confirmation of the diagnosis before admitting his patient.

Selection of an isolation hospital as a poliomyelitis hospital should be based on "the essential triad" of experienced medical personnel (particularly a resident medical officer and a consultant), experienced nursing personnel based on the ward-sister and the staff nurse, and effective liaison with the orthopædic hospital which would be caring for the patients after the acute stage. In epidemics it would be better to extend the facilities within these selected infectious-disease hospitals, if necessary drafting the staff to work under the experienced staff, rather than to send out trained teams; for these would not only encounter new difficulties but would also be a serious loss to the parent hospital, which was particularly undesirable during an epidemic. Dr. Davies regarded as impracticable the suggestion that special poliomyelitis hospitals should be established since, because of the seasonable incidence of the disease, such hospitals would probably be out of work for two-thirds of the year. The peak poliomyelitis period coincided with the most quiet time for other fevers, and was in fact the most convenient for treating poliomyelitis in the infectious-disease hospital.

Diagnosis and Management

Dr. W. RITCHIE RUSSELL discussed early diagnosis and management. He emphasised the importance of early differentiation between poliomyelitis and the various forms of meningitis, including tuberculous, since these now responded well to chemotherapy. Highly characteristic of poliomyelitis was the association of meningitic symptoms with full consciousness; other suggestive factors were complaints of curious pains and paræsthesiæ in chest, thighs, neck, shoulders, and sacrum, and also fasciculation and retention of urine. Diagnosis could never be certain until lower-motor-neurone paralysis developed; but since physical activity increased paralysis, examination of muscle-power should be limited to 2–3 minutes not more than 2–3 times in the twenty-four hours.

Respiratory impairment or difficulty in swallowing necessitated immediate special care. The mortality-rate from poliomyelitis was nearly 10%; the mortality could probably be reduced by a third or half if there was a proper understanding of the modern principles of keeping the air-passages clear. It was particularly important to distinguish the case with respiratory embarrassment due to mucus in the throat or atelectasis, from one with respiratory paralysis. In the former the use of a respirator often led to disaster; all that was needed was to turn the patient prone without a pillow and elevate the foot of the bed 12–18 *inches*. With *skilled nursing*, tracheotomy was rarely necessary. Dr. Russell thought that the most urgent need was for the training of a pool of trained nurses as specialists in the care of the respiratory tract in these cases, who could be called up to help in poliomyelitis outbreaks. Finally, he criticised the present system by which patients were transferred to orthopædic centres after three weeks; he thought that this caused additional psychological trauma to the child, interrupted treatment at the stage when there was a change from inactivity to supervised activity, and had a bad effect on the staff of both hospitals. He would prefer to see the first three months of the illness handled by the same staff, even though this might mean establishing convalescent sections in the infectious-disease hospitals.

Use of Respirator

Dr. A. B. KINNIER WILSON said that there were three main causes of respiratory difficulty in poliomyelitis:

1. *Failure to swallow and to keep the vocal cords apart (pure bulbar poliomyelitis).*—In twenty-four hours these patients secreted 1·5 litres of saliva and all of it must be emptied by the mouth; they should be placed prone and head downwards on a steeply tilted bed, and fed either intravenously or by an indwelling stomach tube. If they were placed in a respirator they died from forced inhalation of the secretion.

2. *Failure of respiratory rhythm from involvement of the respiratory centres.*—Fortunately this was more rare; it was sometimes difficult to distinguish from (3) and sometimes complicated by (1).

3. *Failure of the prime movers of the thorax—the intercostal muscles, the diaphragm, and the abdominal muscles.*—Here there was a loss of vital capacity, and these were the cases which required a respirator—nearly always a cabin respirator—in the acute stage.

A spirometer was valuable for indicating the need for a respirator; in the acute stage a vital capacity of 2 litres or less was an indication, but in the chronic stage patients could often manage unaided on considerably smaller

Letters to the Editor

HAZARDS OF LUMBAR PUNCTURE

SIR,—Your admirable leading article of April 11 suggests that the risks of lumbar puncture are perhaps greater than they should be.

When lumbar puncture is performed for diagnostic reasons, only two simple rules need be observed in addition to those of asepsis. First, a thin-calibre needle should be inserted with the bevel facing laterally and without the preliminary palaver of a local anæsthetic. The fibres of the dura mater run longitudinally, and so, if split and not cut, they will rapidly close on the withdrawal of the needle. Secondly, for the usual biochemical investigation it should not be necessary to withdraw more than 10 ml. of fluid.

In my experience two types of patient are most likely to suffer post puncture headache: (1) those who have lumbar puncture done for a second or third time, and (2) those with disseminated sclerosis—I regard this feature as an additional point in the diagnosis in an uncertain case. These two types of people have this in common, that they are both upset in an emotional sense. Treatment of tuberculous meningitis necessitates daily punctures, and, in those patients I have seen, some of whom had upwards of 400 lumbar punctures, there has been no incident of headache after the first few occasions, when headache is normally a symptom. In my view, therefore, a post-lumbar-puncture headache can be prevented or, when present, can be simply explained.

Edinburgh. JAMES K. SLATER.

SIR,—In your excellent leading article you emphasise that the use of a fine calibre spinal-puncture needle prevents subsequent leakage and makes post-puncture headache rare. You might have added that such a needle will soon become blunted, twisted, and inefficient unless the skin is previously perforated—for example, with a large bore needle of about 5 cm. length, which may also be used, if desired, to anæsthetise down to the dura. I can bear out Hillman's[1] claim that, if the technique be precisely followed, sepsis and trauma can be eliminated and headache almost completely averted. Though this minor procedure is often easy, there are not a few patients in whom it may be difficult, including the elderly with bony changes and those with rigid or twisted spines. The attainment of uniform success in lumbar puncture calls for experience and a careful and exact technique.

Bradford. PETER MCEWAN.

SIR,—Your leader gives a timely exposition of the discomfort of pneumo encephalography, but an "immediate crashing headache, which builds up," is by no means a constant feature. Much depends on the skill of the operator, and I, for one, would seriously question whether a severe and immediate headache is an invariable consequence of the first few cubic centimetres of air reaching the brain.

Nevertheless, the dismay with which a patient faces a second investigation of this kind is often clear and unmistakable. Therefore, it was with some surprise that I found no reference to the essentially humane method of air encephalography under general anæsthesia. This is regarded as a usual matter with small or even adolescent children.

With regard to the headache following replacement with air, which was described as lasting for several days, this definitely follows air encephalography very commonly. Follow-up of anæsthetic cases prompts me to suggest that the long lasting headache is functional, as it does not occur after the same investigation under general anæsthesia.

It is interesting to note that vomiting frequently occurs as air is introduced when the patient is fully conscious but never (in my own series) when the patient is even lightly anæsthetised.

It seems to me that whatever drawbacks may be implicit in complete replacement in order to obtain complete ventricular visualisation, this investigation is likely to become more, not less, widely used. You rightly stress the importance of a small bore needle in the correct space, especially as the technique is so much more likely to be used as operators are encouraged by the aid of an anæsthetic.

The future drawback to air encephalography would appear to be excessive zeal in manipulation in order to conduct the air from one space to another. There is often an interval between "takes," and an anæsthetist may then usefully inspect the films, not only to assure himself that the bevel of his endotracheal tube is not too firmly impinged against the trachea, but also to look for skeletal deformities or other lesions, particularly in the parts involved in manipulation. When the radiologist's attention is keenly focused on an intracranial lesion, he may not always spare thought for routine technique. In any case, the radiologist may have no means of assessing the effect of relaxants given by the anæsthetist.

National Hospital, Queen Square,
London, W.C.1. J. NOEL JACKSON.

SIR,—Your leading article describes fairly and very fully the hazards of lumbar puncture. There are now a large number of anæsthetists who will follow you in your agreement with Kennedy's[1] plea that spinal anæsthesia should be used only when general anæsthesia is absolutely contra indicated, and many will avoid that method in these cases too.

One reason for this, as you point out, is that grave and permanent neurological sequelæ may follow; but in addition—this point was omitted from your article—there is the almost certain knowledge that if permanent paralysis results a claim for negligence will shortly be laid by the patient against the operator, and probably against the hospital as well. The doctrine of *res ipsa loquitur* will be pleaded and the onus of rebutting negligence therefore becomes the duty of the defendants. It is most noticeable that in actions of this nature and other negligence claims a contest between the several defendants exists. The Ministry of Health has directed that hospitals which have to pay damages to patients for negligence must try to obtain a contribution from the doctors concerned.

I will agree that examination of reported cases of permanent palsy following spinal anæsthesia sometimes shows clear evidence of careless work, or errors in technique which should not have been made by that particular operator. On the other hand, there still remains a small hard core of cases gravely injured after spinal anæsthesia, in which the most exhaustive examination fails to reveal any evidence of negligence. Gunnar Thorsen[2] analysed 2493 cases which had undergone spinal anæsthesia. He found that the frequency of permanent neurological symptoms of one kind or another was at the rate of 1 in 200 cases. Allowing that this complication-rate may be very high, Thorsen was unable to find a cause for the resultant paralysis in 25–30 of these cases.

These were accidents in the true sense of the word and such cases may have been in your own mind when you wrote: "it may sometimes be difficult to decide whether symptoms following spinal anæsthesia are due to the lumbar puncture or to an unusual reaction to the anæsthetic."

WORK STUDY

W. D. SEYMOUR mentioned some effects of varying the speed at which a simple repetitive industrial task is carried out. The durations affected were those of the "grasp" and "position" phases—not, as one might have thought, the movement phases. From this he developed his view of the pre-eminent importance of the perceptual factor in manual operations.

The Wider World

THE BIGHT OF BENIN AND BEYOND

SOME EXPERIENCES IN THE COLONIAL MEDICAL SERVICE*

Sir SELWYN SELWYN-CLARKE
K.B.E., C.M.G., M.C., M.D. Lond., F.R.C.P.
A PRINCIPAL MEDICAL OFFICER, MINISTRY OF HEALTH

WHY do people choose to leave this excellent country of ours and wander abroad? Is it a form of masochism to want to go to a part of the world, for example, which in my early days overseas was called "the white man's grave"? In the hot and steamy country bordering the Bight of Benin, you live in a bath of perspiration for several months of the year and you are wet with sweat almost as soon as you have dried yourself after a tepid shower. Further inland, when the *harmattan* blows from the Sahara and your furniture, floors, and doors go off like pistol shots as they dry and contract, your nose and lips often crack and bleed. Mosquitoes, carriers perhaps of the plasmodium of malaria or the virus of yellow fever, bite you from dusk to dawn and sometimes during the daytime too. The tsetse fly, with its sleeping-sickness trypanosome, or the smoky-winged chrysops, with its filaria blood-worm causing Calabar swelling, or the vicious midge, *Simulium damnosum*, with its filaria of onchocerciasis, bringing joint swellings or even blindness, may all dog your footsteps. "What a gloomy prospect," you say.

If you were to ask me why I chose a career that took me to such places I think that I should reply that it was partly the result of a dislike for general practice, which seemed to be the only alternative in those days. Why didn't I like being a general practitioner? Chiefly because I disliked asking patients for a fee for a consultation or a visit when I realised that some of them, at any rate, could have the treatment I advised or pay my fee, but not both. And I don't think that I really enjoyed delivering a gipsy woman in a caravan (the old-fashioned horse-drawn kind), with no hot water and with many flies and other insects to cope with. So I joined the Colonial Medical Service and left Liverpool for the Gold Coast in October, 1919.

The Gold Coast

I disembarked at the administrative capital of the Gold Coast, Accra. In 1920, there was an outbreak of smallpox in the Gold Coast, and I had to enlarge the infectious-diseases hospital near Accra by building a large number of huts. The mortality was rather more than 1 in 4—27·8%. To lessen the risk of carrying infection into the densely populated town, I established a cemetery fairly close to the hospital, for the main cemetery was on the far side of the town. But the African superintendent of this hospital used to complain to me that he was "humbugged" and kept awake at night by the ghosts of those buried in this cemetery. One morning, however, I found him in a more cheerful mood. He told me that he had had the graves sprayed with 2% 'Izal' and that this had driven the ghosts away so that he could now sleep in peace.

In those days death certificates from one of the very old African registered medical practitioners sometimes needed rather careful scrutiny. One I received said that a labourer from the Northern Territories had died from "exhaustion due to overwork." This seemed a little unusual in a West African, so I went to inspect the body of the deceased. I found that he had been sharing a room about 12 ft. by 10 ft. with seven or eight other labourers. He was lying on a sleeping-mat and there was "coffee-grounds" vomit over his face, singlet, and blanket. His conjunctivæ were deeply jaundiced. At a post-mortem examination we found that the tissues were heavily bile-stained and there were typical petechial hæmorrhages in the gastric mucosa, with altered blood in the stomach. The liver was fatty, and there was an acute nephritis, with a very small quantity of highly albuminous urine in the bladder. On section, the liver showed the typical degenerative changes produced by yellow fever, from which he had, of course, died.

When I first went to West Africa, thirty-three years ago, it was thought that yellow fever in Africa was confined to a comparatively narrow strip along the coast 200 to 250 miles in depth, stretching from St. Louis (above Dakar in French Senegal) in the north to Northern Angola in the south. It was thought that the disease had existed so long in this region that the Africans had developed some racial immunity and only suffered from the disease in a mild form. Several research-workers felt that yellow fever resembled malaria in this respect. It was a matter of common knowledge that, although malaria killed a great number of infants, those who survived and staggered around as pot-bellied youngsters with huge malarial spleens, grew up with spleens that gradually receded under their ribs until they were only a little larger than normal and might even be impalpable.

The brilliant work of members of the Rockefeller Foundation and of the colonial medical services of the United Kingdom, France, and other countries has now established that yellow fever extends across Africa to the Rhodesias, Uganda, Somaliland, Eritrea, Kenya, and the Sudan, and that it can be carried by many different species of mosquito besides the tiger mosquito (*Aëdes argenteus*) or *A. aegypti* or *Stegomyia fasciata* as it used to be called. In those days, therefore, it was thought that one of the best ways of avoiding yellow fever was for Europeans (the so-called non-immunes) to live in segregation areas separated from African dwellings by a building-free zone of a quarter of a mile in depth. No properly brought up yellow-fever mosquito could, it was thought, fly more than a quarter of a mile. Curiously enough, this was not so ridiculous as it sounds, always providing that intensive anti-mosquito measures were taken within the area itself: for the commoner carrier of yellow fever does show some preference for breeding in and near dwellings. Nowadays, with inoculation and with residual spraying with D.D.T. and gammexane there may be less justification for racial segregation on health grounds alone. Time after time, there were epidemics of yellow fever among white people in areas where both the so-called immunes and the non-immunes (local Africans on the one hand, and immigrants, whites, and Syrians on the other) lived close together. It was not uncommon for yellow fever to kill in five to six days: and although the famous Japanese research-worker, Hidego Noguchi, survived for a fortnight, the next victim, W. A. Young, our director of medical research, who had been helping me to investigate how Noguchi became infected, died within six days.

Another disease, in which fever and jaundice are almost invariable signs, is relapsing fever, and I met with it in West Africa for the first time in 1923. In tion in a large catering department) cites a field in which ordinary indices, such as cost per meal per patient, undoubtedly apply We had in mind the situation in regard to medical and nursing staff—where the cost of a doctor in charge of a department may vary from the minimum for the grade up to the maximum plus distinction award In such cases the financial cost figures may be relatively uninformative compared with figures based upon numbers of individuals or sessions Our main point was that the hospital service is a field in which it is essential to work out a battery of indices giving maximum information We had no wish to suggest that " because hospitals treat patients, business methods are not applicable " What we ask is that the methods should be common-sense adaptations to the special problems, not merely conventional systems applied wholesale —Ed L

* Based on a talk given to the Whipps Cross Hospital Medical Society on Oct. 3, 1952.

POLIOMYELITIS

Sir,—In your leading article of Jan 10 you advise physiotherapists to introduce without delay active vigorous exercises to the point of fatigue in the treatment *of poliomyelitis This belief is in accord with that of* Ritchie Russell, who has failed to confirm that deliberately induced fatigue harms paretic muscles in the recovery stage

The *following case appears to* disprove this dictum

An intelligent girl of 10 was admitted to Pinderfields Hospital, Wakefield, on Sept 6, 1949 She was taken ill on Aug 18, and on admission she was found to have extensive paralysis of the right leg and partial paralysis of the left leg She stated that she had recovered the use of the right leg slightly prior to admission

During her stay at the isolation hospital she was given daily passive joint movements After admission to Pinder fields there was no pain or muscle tenderness She was started on sling and spring exercises, and treatment in the water tank She was allowed to sit up in bed On Oct 10 —i e, after about five weeks' treatment—there was a surprising relapse in the condition of the right leg The relapse involved the whole limb, and the greatest muscle changes were

	Sept 10	*Oct 10*
Calf	3	0
Tibialis anterior	3	0
Tibialis posterior	3 +	0
Extensor hallucis longus	3 +	0
Extensor digitorum longus	3	0
Peronei	3	0

The results were checked by two experienced orthopædic surgeons and the senior remedial gymnast

Further inquiry revealed that the girl had been advised by her parents to try to get better as quickly as possible The patient told us that she had been getting out of bed daily and trying to stand, and she had also been exercising her legs as much as she possibly could while in bed She herself had noticed that the right leg was rapidly becoming weaker

All treatment was stopped and she was kept at rest in bed The extensors of the big toe and other toes began to recover slowly, and were showing flickers of contraction by Oct 31 On Dec 20 she started walking with a calliper, but it was not until Jan 1 that there was any appreciable recovery in the muscles On that date tibialis posterior was 3, but the calf remained completely paralysed Tibialis anterior peronei, and extensor hallucis longus recovered to 3 but extensor digitorum longus remained at 2 On Jan 27 she went home and had outpatient treatment at her local hospital

At a review on May 3, 1950, there had been further slight recovery, extensor digitorum longus was now 3, but the calf muscles were still completely paralysed No further recovery was noted during the subsequent follow up

This patient had passed the acute stage of the disease and exercises were given, probably to the point of fatigue There was a definite relapse and, in spite of subsequent complete rest the condition on discharge was worse than when she was first admitted to hospital

I should like to see much more definite proof that active vigorous exercises to the point of fatigue are beneficial, rather than harmful, before advising such a technique If the ultimate muscle recovery is going to be jeopardised, even in occasional cases, by the adoption of this method, then its use must be questionable The saving of a few weeks', or even months', treatment in hospital should never be allowed to prejudice the end-result in poliomyelitis

Leeds GEOFFREY HYMAN.

TOO MANY DOCTORS?

Sir,—In your leading article last week you say

> " Oddly enough there are still too few applicants for junior posts as house officers, senior house officers, and registrars in the peripheral hospitals This is partly due to an absolute shortage, but it also to some extent reflects unequal distribution "

As a student about to enter my final year of study, I would point out that a compulsory preregistration year in hospital may appear satisfactory to the authorities, but with the individuals concerned it is not altogether popular Is it not possible that one reason for a shortage of house officers is the pay that they receive ? £350 minus £100 for board and lodging is not much on which to keep a wife and home After six years' work at a university ex-Servicemen who have a wife to support are not going to rush to jobs that hardly keep the wolf from the door In years past between graduating and starting a house job, a newly qualified doctor could earn some money as a locum tenens in general practice and so augment the pay he was to get from his hospital posts This is not possible now, and the financial problem becomes even more acute

This compulsory year in hospital may fill the posts that cannot be filled voluntarily, but is it of benefit to the young doctor who is going into general practice ? Hospital practice is hardly the same as general practice Instead of two six month periods in two departments of a hospital, rotating internships in large hospitals, so that young doctors did three months in the main departments, would be far better

To fill the posts just senior to that of house officer will require one of two moves either better prospects in the hospital service, or compulsory service

Edinburgh G I SLATER

PHARMACEUTICAL ADVERTISEMENTS

Sir,—If Sir Reginald Watson Jones will look again at my letter of March 28 he will see that I applied the word " pernicious " only to the way in which commercial leaflets tend to replace the more orthodox forms of teaching Perhaps if manufacturers of splints enclosed detailed instructions on how to treat fractures he, too, would object He says (April 11) that I complain that " British pharmaceutical firms are not fair or just " The words are his, not mine Everyone knows of the foundations, endowed chairs, and other forms of financial support by means of which the great commercial firms in this country have enriched science Not the slightest criticism was levelled against such ethical firms My letter was referring to some of the manufacturers of antibiotics It is well known that streptomycin, neomycin, aureomycin, and chloramphenicol were all discovered in America, and all the vigour of his language will not alter this simple fact If the facilities offered here are as good, or even better, as he seems to suggest, then the explanation would be that our young research workers are inferior Surely this cannot be his belief

I feel that makers of antibiotics would be well advised if a greater part of their financial reward was spent on medical research and less on circulars In the U S A vast numbers of publications carry the words " supported by a grant from " followed by the name of a commercial firm This is legitimate advertising which benefits of the hospitals were persuaded to discard Eastern herbal treatment, except for a few paying patients. They agreed to treat all cases of cholera, smallpox, typhus, cerebrospinal meningitis, leprosy, and so on, in isolation hospitals and leper settlements, and to segregate patients with pulmonary tuberculosis in special wards.

At the same time, the status and training of nurses were improved beyond all knowledge. The old custom was for nurses to pay 6 dollars a month for their food and to receive no pay for the first two years of their service. Many of them came from families by no means well off, and they lived by accepting money from patients. For example, a patient paid 5 cents for a glass of water and 5 or 10 cents for a bedpan. I was able to persuade the directors to forgo the monthly payment from nurses; and then I gradually got them to agree to pay the nurses an allowance, followed later by a small salary and eventually by the same scale of salaries as in Government hospitals in Hong-Kong. Sister-tutors were introduced and the standard of training was raised until Hong-Kong could claim recognition by the General Nursing Council and the Central Midwives Board for its nursing and midwifery certificates. To fulfil the midwifery regulations, a short course in the United Kingdom was also required.

After the surrender, life became very hard for those who survived the dreadful days of actual fighting. Such civil hospitals as the Japanese allowed to function were manned entirely by Chinese, Eurasian, or neutral nurses and doctors. All the English matrons, sisters, and doctors were interned in a concentration camp. Many of the British and others who were interned took with them only what they could carry. They lived on meagre rations for forty-four months under extremely congested conditions, with no privacy of any kind.

The Chinese and Eurasian staff who—instead of escaping into free China—remained on duty at my request in order to maintain at least a skeleton of the medical and health services, carried their lives in their hands. They were humiliated, insulted, and maltreated, and in several instances "investigated"—with all that that means—and imprisoned for their loyalty to the British cause.

Before the war spread to the Pacific, many Chinese died of beriberi, many wards of the Chinese hospitals were full of patients with beriberi and pellagra, and thousands died of tuberculosis. Despite all this, when peace returned the death-rate and infant-mortality rate fell to a third, and there were few cases of frank deficiency disease—an unlooked for result of nearly four years of semi-starvation under Japanese occupation.

The Seychelles

I left Hong-Kong for the Seychelles in 1947. These islands are spread over thousands of square miles of the Indian Ocean: one-third are of granite and two-thirds of coral. About a third are inhabited by descendants of 18th-century French colonists and their African slaves, and by descendants of slaves freed from Arab dhows by our naval frigates in the middle of last century. There are also a few British officials, Indian and Chinese merchants and their families, and some retired officers of the Army and Indian Civil Service. The island of Mahé, the seat of government, lies only 4° south of the Equator, but it is free from hurricanes, venomous snakes, and anopheline mosquitoes.

The coconut provides the livelihood of the Seychelles: it is exported in great quantities as copra, the dried flesh of the nut. The coconut tree has several enemies: a small brown beetle attacks the lower part of the trunk: a large rhinocerus beetle shears off the young fronds: a minute yellow or black scale grows on the leaves and stifles the tree; and rats attack the growing nuts. Where plantation owners are careless, rats may spoil as much as a third of the crop. The government offers 5 cents for a rat's tail and distributes rat poison free; and owls have been imported from Kenya to catch the rats. The scale alone would have destroyed all the coconut plantations by now had not a clever entomologist, Vesey Fitzgerald, found a ladybird which attacked the scale and kept it in check.

Intestinal infestation by round, hook, and whip worm is very common and causes much ill health. Disposal of sewage and refuse is still primitive, particularly in the more rural areas. A debilitating type of dysentery is found in the Seychelles, amœbic and lamblial forms being far too frequent, and the amœbic type is associated with an unusually high prevalence of liver abscess. The damp hot climate seems bad for patients with pulmonary tuberculosis, which is a fairly common cause of illness and death. There is leprosy too; but almost all the infectious patients are isolated on Curieuse, one of the many islands.

The suicide-rate is rather high, but serious crime is comparatively rare and usually follows a drinking bout. A peculiarly obnoxious drink called *purée,* made out of fermented bananas, pineapples, cassava, and other ingredients, topped up with illicit rum distilled from sugar-cane, has a deadly effect and is responsible for most of the trouble. The Seychelles government itself brews *bacca,* a beer-like drink made from fermented fresh sugar-cane juice, and encourages the inhabitants to drink this instead of the more potent *purée* or rum.

Although the Seychelles are a bit uncomfortable at times, they are particularly interesting and beautiful islands; and there are many friendly and kindly people of all colours, races, and creeds. I shall never regret having spent there the last few years of my Colonial service.

Envoi

To those who are smitten with wanderlust, or who are imbued with a spirit of adventure, or who are interested in trying to help the less developed members of the British Commonwealth to attain a higher standard of living and health, I commend the Colonial Service. The work is often in virgin soil, which is so rich that it produces an unusually good crop, altogether incommensurate with one's efforts.

Parliament

The Social Services and the Budget

SEVERAL references to the social services, including the National Health Service, were made in the budget debate. Mr. R. A. BUTLER, in introducing his budget, pointed out that the social services took 60% of civil supply expenditure—£1264 million. This was an increase of £80 million on last year. Of this increase £24 million was due to there being a full year's cost of the increases in social benefits made in the last budget. The National Health Service, excluding Civil Defence, would cost £411 million, an increase of £18 million, due mainly to rising costs, of which the outstanding example was the Danckwerts award. Education, including the universities, would also cost £27 million more than last year—£286 million.

Of the remaining £567 million, Mr. Butler said that £128 million would go to National Assistance; £183 million to National Insurance and family allowances; £89 million to war pensions; £70 million to housing grants; and £68 million for Exchequer contributions to local revenues. For food subsidies in 1953–54 he had provided £220 million, which compared with the rate of £250 million which he had set in last year's budget.

SOME PRIVATE ENTERPRISE

Wherever appropriate, he believed that the Government should do less and the private citizen more. During the past year by following this line he had introduced some flexibility and more economy. Thus we were entering into a new phase in our housing policy, in which

Although we are unwilling to challenge the histological identity of various types of kernicterus, there must remain considerable doubt about extending this identity The sequelæ in certain children who have survived the neurological damage associated with icterus gravis are well established, these children present definite syndromes most fully and recently described by Gerrard [7] Despite much attention to the development of surviving premature infants there is no evidence which would suggest that their nervous systems have been subjected to any such specific damage Intrinsic pigmentation of the primary dentition is a further feature of icterus gravis which has not so far been described in any other group of children [8]

It appears, therefore, that whatever the measure of identity between the various types of kernicterus some mechanism other than anoxia, anæmia, or blood group incompatibility explains its onset, and this is probably associated in some way with pigment metabolism

RARE COMPLICATION OF CHICKENPOX

SIR,—I was interested to see your annotation of April 11 I have just had a case of chickenpox in a married woman of 32, in whom a troublesome cough began the day after the rash first appeared Two days later she sent for me because paroxysms of coughing were making her short of breath She looked very ill, was too weak to sit up, and had bloodstained sputum The only signs I detected in the lungs were rapid respiration and scanty, generalised rhonchi Her condition was unchanged for two days, and thereafter she made a gradual recovery

P R BOUCHER

PRIMARY REPAIR OF SKIN DEFECTS WITH LOCAL FLAPS

SIR,—It is to be hoped that surgeons will not be carried away by Mr McLaughlin's enthusiastic advocacy of local flaps for the primary repair of skin defects (April 11) Such flaps occasionally necrose, leaving a defect as large as, if not larger than, the original, and the incidence of necrosis varies inversely with the experience of the operator Apart from primary trauma, it must be very unusual for any surgeon to be confronted *unexpectedly* with a large defect in urgent need of immediate repair, since such defects are created by the radical removal of surface lesions, the extent and depth of which can commonly be assessed or at least suspected on clinical examination before operation In other words, the need for a local flap and the design of such a flap can be decided in advance, and it is here that the plastic surgeon with experience of these methods can be of the greatest assistance

In traumatic surgery, and particularly in hand injuries, the need for immediate cover with a vascular skin flap frequently arises, and the technique of such operations is fairly widely known All the illustrations of Mr McLaughlin's paper, however, and most of his remarks, seem to be concerned with defects created by the excision of either malignant or septic lesions and it is very doubtful if primary repair by local flaps of these defects is justifiable apart from two small groups of cases The first group is those defects whose base is unsuitable for free skin grafting because of exposure of extensive areas of denuded bone, tendon, or ligament exposure of the dura or the pleura, or an opening into one of the body cavities The *second group* is those malignant lesions which have recurred after irradiation, and in which it is desired to give further irradiation after excision The use of a local flap of non-irradiated skin will permit this But these instances can almost always be foreseen and planned for in advance, with the aid of a plastic surgeon if necessary, and in most other cases the use of a free skin graft is much more satisfactory, and in malignant cases frequently obligatory Some doubt must always exist as to the completeness of the local excision of a malignant skin lesion no matter how radical the operation, and surely it is wiser to cover such a defect with a thin free graft, and so allow early recognition of any recurrence, than *to mask the area with a thick local flap*, the use of which opens up widely neighbouring tissue planes

We feel that Mr McLaughlin dismisses too lightly the use of free skin grafts They are simple to cut and apply They take readily on freshly cut tissues (with the exceptions mentioned above) Their cosmetic appearance is not always good, but in certain situations they are preferable in this respect to local flaps as a permanent repair The use of free full thickness post auricular skin grafts around the eyelids and nose, or full thickness or thick split grafts for certain defects of hand and fingers, are two examples In other instances they should be regarded as a simple, quick method of achieving immediate temporary cover They then avoid the use of a hastily planned local flap at the end of an extensive operation, they allow a definitive secondary repair to be planned and carried out at leisure and under ideal conditions, they allow skin to be prepared and brought from a *distance when necessary*, *and they allow the delay* of the secondary repair until the risk of local recurrence of malignant disease is minimal

Two of the illustrations invite further comment The repair shown in fig 3, excellent as it is, is only made possible by the lax neck skin of the aged, and might well be disastrous if attempted in a young adult The procedure shown in fig 7 is practically impossible as a *primary* repair, since the inturned flaps must hinge almost on the margin of the excision and would be unlikely to survive Even when carried out as a secondary repair it is frequently better to " delay " such flaps before rotating them into position

THE PROBLEM OF PEPTIC ULCERATION

SIR,—Sir Heneage Ogilvie (March 21), " at the risk of giving offence," criticised the work of the late Hedley Visick This criticism is obviously sincere, and I hope Sir Heneage will understand if I reply in the same spirit to some of these criticisms and that he will forgive me if I endeavour to correct a misconception

Visick's policy of high gastrectomy was only *undertaken* after much deliberation and discussion, and was more likely the result of undue optimism than a " policy of despair " The primary reason was that early in the series we encountered 5 recurrent ulcers (3 following Polya and 2 following Billroth I resections), these were *submitted* to further and more radical resection, the Billroths *being* converted into Polyas As all 5 patients remained well without further recurrence, it *seemed reasonable gradually* to increase the initial extent of the resection *In my* analysis I tried to indicate this point by classifying 201 patients as " developing measured radical gastrectomy " There is little doubt that a high resection does give a practical, if not an absolute, immunity *from recurrence* but I do agree that the removal of too much stomach is unnecessary and is *one, but only one of the factors* that lead to postprandial symptoms *The difficulty is* to define what is meant by " too much," *for there appears* to be an optimum degree, and it was this *ideal which* Visick was seeking, he hoped that by *measuring the* extent of the stomach remnant, and later *assessing the* results, it would be possible to estimate it It is true that towards the end of the series Visick was abandoning the

employed in the nursing services of the Crown; 2650 in school nursing; and 4000 in industrial nursing. In hospitals 11,501 enrolled assistant nurses were employed full-time, and 5300 part-time. The number of beds in these hospitals was 516,114, of which 28,502 were unstaffed.

No information was available as to the number of married women nurses employed. The numbers of male nurses employed in hospitals were 25,178 full-time and 315 part-time; there were no separate figures for male nurses employed by local health authorities, but the number was known to be small. No records were available of the wastage of trained nurses. Hospitals estimated that they required 10,420 additional trained nurses and local authorities 1331.

Hospital Medical Staffs

Mr. A. BLENKINSOP asked the Minister of Health what total reduction in the medical staffs of teaching and non-teaching hospitals he anticipated during the current financial year.—Mr. IAIN MACLEOD replied: I cannot predict the results of the special review of medical staff which I have asked hospital authorities to make. Mr. BLENKINSOP: How many of the registrars are likely to go out of practice during the next 12 months?—Mr. MACLEOD: There is no particular pressure being put on the Ministry of Health in that matter, although it is a difficult one.

Dr. BARNETT STROSS: Is the Minister not aware that many hospitals are finding difficulty in obtaining junior registrars? Has he considered helping them so that they may have the necessary help to carry on their work?—Mr. MACLEOD: The figures for junior registrars have been for some time very closely in accordance with the planned schedule laid down by the Labour Government. There are difficulties there, but the total number of specialist posts becoming available is, unhappily, not as high as was hoped when it was laid down. Mr. BLENKINSOP: How is it, then, that there has been a big drop in the provision made in the estimates for medical staff of the teaching and non-teaching hospitals?—Mr. MACLEOD: The hon. Member is fallaciously comparing this year's estimates with those of last year instead of last year's outlay. There has, in fact, been no change.

Mr. BLENKINSOP asked the Minister if he would give the number of senior registrars whose appointments were being terminated and for whom there were not likely to be vacancies in hospitals; and what action he proposed to take.—Mr. MACLEOD replied: I regret that this information is not available, as the number of hospital vacancies cannot be predicted with any accuracy. I am, however, reviewing the position in consultation with representatives of the profession.

Central Purchasing of Stores

Mr. BLENKINSOP asked the Minister why he proposed to reduce the amount of central purchasing of general medical and surgical stores and appliances, and drugs and vaccines in the current financial year, in view of the economies that had been effected by central purchasing in the past.—Mr. MACLEOD replied: The reduction in estimated expenditure on these supplies in 1953–54 is due mainly to revision of the estimated amount of direct purchases for other Government departments. The amount of central purchasing and contracting for the National Health Service has not been reduced. Mr. BLENKINSOP: Are we to understand that there has been no change of policy to encourage a gradual development in suitable fields of central purchases for the health service?—Mr. MACLEOD: If I can secure economies through this method or any other I will do so.

Dental Treatment and Appliances

In answer to a question, Mr. MACLEOD stated that the numbers of applications made for conservative dental treatment and dental appliances, respectively, in the months of October, November, and December, 1951, and during the corresponding months of 1952 were as follows:

—	1951			1952		
	Oct. (5 wks.)	Nov. (4 wks.)	Dec. (4 wks.)	Oct. (5 wks.)	Nov. (4 wks.)	Dec. (4 wks.)
Conservative dental treatment ..	495,000	363,000	388,000	496,000	414,000	333,000
Dental appliances ..	172,000	124,000	92,000	151,000	121,000	74,000

Public Health

HOUSING LONDON'S TUBERCULOUS

William Farr[1] in 1841 was the first vital statistician to stress the constant relation between the density of a population and its mortality experience. Farr's "law of mortality" postulated that the crude death-rate for districts in England and Wales increased as the sixth root of the population density per acre. In 1922 Brownlee,[2] using standardised mortality-rates, demonstrated that the death-rate for each borough in London was constantly proportional to the tenth root of the density of its population. The more favourable position of the Metropolis in this respect was attributed to the peculiarities in the age-distribution of London's population and in its age-specific mortality-rates. While total mortality may no longer everywhere show this constant parallel between house density and death-rates, there is still a close correlation between tuberculosis morbidity and mortality and crowding of and within houses. Shirley Murphy,[3] London's first county M.O.H., showed how regularly the tuberculosis death-rate in London increased with every rise in the proportion of people living more than two per room; and Robert Koch,[4] discussing "the manner in which tuberculosis takes place," stigmatised this infection as a disease of crowded dwellings.

Improvement in overcrowded-living conditions is not, however, necessarily followed by improved mortality-rates. Newsholme[5] pointed out that, although overcrowding is one of the important consequences of urbanisation that have an adverse effect on tuberculosis rates, beneficial influences such as improved wages and nutrition could nevertheless reduce mortality even in the presence of overcrowding. M'Gonigle[6] clearly demonstrated how the mortality-rate of a rehoused population increased considerably if poor nutrition was allowed to replace overcrowding as an adverse influence. This observation has now been confirmed indirectly by Benjamin[7] in a statistical study of the individual social factors affecting tuberculosis morbidity and mortality in London boroughs. If, then, tuberculosis can and does wane in a district in spite of adverse housing conditions, it might seem questionable, in these days of universal housing shortage, to select the tuberculous for specially generous treatment in the relief of overcrowded living conditions. Moreover, Hartston,[8] in a study of the prevalence of tuberculosis among the contacts of registered London cases, observed that by the time a case is recognised, most of the susceptible contacts have already been infected. By the time the patient has been rehoused all susceptible contacts have been abundantly exposed, and new cases in the household thereafter are uncommon. This may also explain the rarity of new cases of active tuberculosis among the child contacts of colonists at special village settlements.

Does this mean that rehousing of the tuberculous, when it comes, is too late? Should preferential rehousing of overcrowded dwellers be given to those families with young children and adolescents *before* a case of tuberculosis has appeared among them? These questions were considered by the London County Council Chest Clinic

Friday can have stood outside it—and his parrot might have had words to utter even on this exception

The relationship of trust is manifestly an accident and not the substance of a profession, and this substance has been wisely said to be the fact that the activities of a profession are properly subjected to theoretical analysis and are modified by conclusions drawn from that analysis This process involves the understanding of the natures of the factors involved in these activities Thus, the practice of a profession cannot be disjoined from its theoretical understanding When it is so disjoined it ceases to be a profession and becomes a craft or a technique

This is the criterion by which we may judge the claim to professional status of the ancillary services used by the doctor unless the word "profession" is to be trivialised and to become as meaningless as the word "esquire"

Because everyone in a hospital from matron to ward-maid, from almoner to stenographer, is the doctor's colleague in the sense that each contributes to a common end, it is not rational to assume that each and every one is a member of a profession

Mr Farrer-Brown is kind enough to concede that the doctor must be the leader of the "team," adding that if he is to be a real leader he must have distilled his own and his colleagues' knowledges and experiences This is woolly nonsense, incapable of precise or clear analysis, having only the dubious merit of making his remarks emotionally palatable to a non-medical audience

The doctor's primacy in hospital or at the sick bed rests upon no sentimentalities or snobberies, but upon the scope and quality of his experience, upon his being something more than a craftsman, and, finally, upon the fact that on his shoulders rests the ultimate responsibility in a measure that his subordinates could not bear and would not accept No playing with words that weakens the hierarchy upon which the rational and humane practice of medicine rests should be allowed, and, while Mr Farrer-Brown may not wish to upset it, his tendentious alternative "medical leadership or medical domination" reveals his dangerous failure to understand the complex problem upon which he pontificates so glibly

It is a symptom of this disorderly age that we should find the newest occupation publicly lecturing the oldest profession Long since, when I was young, this activity was known as teaching your grandmother to suck eggs It has never been a highly regarded occupation, or should I say profession ?

London W 1 F M R WALSHE

SIR,—Many of us will have read Mr Farrer Brown's address, with great interest but much searching of the soul But we must surely repudiate his attempt to apply the word "industry to the National Health Service, not at all from pride, but merely out of respect for the Queen's English The relevant definition in the *Concise Oxford Dictionary* is "branch of trade or manufacture," which the National Health Service is not—or certainly ought not to be

Nevertheless it is true that a drastic change in the crazy patchwork of its organisation is bound to come Whatever their faults the medical services of the Forces during the war represented the most highly integrated health services in the history of the world A professional hierarchy from the director general down carried out its duties free from the stultifying control of lay committees Grievances could be raised in Parliament and effectively redressed Perhaps it would be desirable for a similar hierarchy to be established in the National Health Service Before this could be achieved a very thorough rationalisation of local government would be essential

London W [illegible] GEOFFREY G SHEPHERD

SIR,—Mr Farrer-Brown asks for better protection of the public against the incompetent doctor Surely some protection is already provided by the right of every patient to choose his general practitioner and to change, if he so desires I believe that it is as important for the general public to want a good health service as it is for the medical profession to try to make one

Harrow L PICTON DAVIES

Obituary

JOHN GUY

M D Glasg , F R F P S , F R C P E , D P H

Dr John Guy, formerly medical officer of health for the city of Edinburgh, died at his home at Aberlady, East Lothian, on April 11, at the age of 79

He qualified in Glasgow in 1894 and took the D P H at Cambridge in 1899, and the following year proceeded to the degree of M D Before going to Edinburgh he had held posts as assistant police surgeon at Bradford, resident medical officer in poor-law hospitals there and at Leeds, and superintendent of the sanatorium at Bridge of Weir, and for a short time he was tuberculosis officer for Gloucestershire He was elected a fellow of the Royal Faculty of Physicians and Surgeons in 1911 He first joined the staff of the Edinburgh public health department as tuberculosis officer in 1913, and in 1913 he became a fellow of the Royal College of Physicians of Edinburgh Later he was appointed assistant M O H , and deputy M O H , and in 1930 he became M O H for the city He was given this appointment at the time when, under the Local Government Act of 1929, the city took over the former poor-law institutions and hospitals and reorganised its curative medical services He was therefore responsible, in cooperation with the University of Edinburgh, for the conversion of the former poor-law hospitals into general teaching hospitals Thus, the Western General Hospital, formerly Craigleith Hospital, was gradually transformed into an effective general hospital staffed largely by members of the university teaching staff The process was slow, but internal renovation and some new building was undertaken Dr Guy acted, in effect, as administrative superintendent of this and the related hospitals

[Scott & Pictorial Press

Dr Guy was also a lecturer on public health in the university, on tuberculosis at the school of medicine of the Royal Colleges, and on hygiene at the School of Social Study in Edinburgh He collaborated with the late Dr Linklater in a textbook on *Hygiene for Nurses*, and he also wrote a monograph on pulmonary tuberculosis

When he retired in 1938 he went to live on the Island of Coll one of the Inner Hebrides, where he spent the years of the war Afterwards he returned to East Lothian living first at North Berwick and for the last four years at Aberlady

Dr Guy is survived by his wife, three sons, and one daughter

FREDERICK WILLIAM EDRIDGE-GREEN

C B E M D Durh , F R C S

Dr Edridge-Green, who died on April 17 at the age of 89, was the inventor of the first efficient test for colour-blindness His colour-perception lantern is used by the Royal Navy and the railways, and his bead test is used by the National Service boards In 1920 a medical director-general of the Navy wrote "Dr Edridge-Green has deserved well of his country He has given us the means of averting appalling disasters by eliminating the colour-blind from control of vessels and fleets at sea"

A Running Commentary by Peripatetic Correspondents

WHEN I am reading a book or a paper in a dream the content seems very clear, and I have a feeling that it is of supreme importance to the human race. But when I wake I cannot remember a word of it. One night last week, however, I was reading obituary notices in *The Lancet* sometime in A.D. 2053. I managed to make some notes as soon as I woke.

The first was of Sir Passit Wellup, O.C.C., chief consultant in cardiac catheterisation (left-sided) to the Ministry. He started to specialise while still at his preparatory school, and studied cardiology for his General Certificate of Education. He took his M.B. in catheterisation, and inclined towards the left immediately after he qualified. He figured in a famous lawsuit in the early years of the century when he was prosecuted for trespass by the Association of Consultant Catheterisers (Right-sided). They alleged that his catheter once passed through a septal defect, natural or (they underlined the "or") maliciously manufactured, and investigated the right ventricle. He was lucky to get off. He sat back with enhanced reputation to invent an anti-dextro-loculus radar catheter tip which prevented repetitions of this painful contretemps. He was one of the first to benefit by the Celibacy of Consultants Act, passed in 1990, owing to the repeated moans from registrars that they could not afford to keep their families on £1500 a year. Being celibate and childless, Wellup could take his statutory five months' holiday per year at all the best seasons, and Madeira, Switzerland, the Riviera, Mars, Blackpool, all the favourite haunts of the consultant, were known to him. He lived to the age of 95, passing catheters to the last. He once did three days' locum in general practice, and though he had to conceal this fact from selection committees he admitted it to his closest friends, and even went so far as to say "It wasn't as bad as all that."

Next there was Dr. Rubber Stamp, a well-known general practitioner, who died at the advanced age of 45, from coronary thrombosis. High-lights in his career were the Compulsory Marriage of General Practitioners Act (2031), which increased the number of unpaid overworked Civil Servants considerably, and the fact that he once achieved the impossible by calling out ten consultants in one Sunday afternoon.

Perhaps I dreamt this wrong. I like to think so. Perhaps this is what I read:

Dr. Good Type, who died at the age of 90, was one of the few doctors who could remember the days when there were such things as consultants and M.O.H.s, and even a College of General Practitioners. He was a pioneer in the legislation which made it compulsory for general practitioners to have been registrars, and for consultants to have been general practitioners. He also supported the movement to abolish the medical schools and institute the apprentice system. At a time when the artificial divisions of consultant, registrar, houseman, and M.O.H. still existed, Type already held his own infant-welfare clinics, gave prophylaxis to his own patients, inspected their own drains, and wrote letters to consultants which gave them a magnificent picture of the background of the patient as well as a very sound clinical diagnosis.

Did I wake up then, or was I just quoting from memory from the obituary of my own great-grandfather, who was a J.P., a respected surgeon, a G.P., M.O.H. for the county borough, and a fellow of the Royal Photographic Society to boot?

* * *

For those who have never run aground in a small cabin cruiser I can recommend it as an interesting experience. As the boat heels over gradually to one side, though never to the point of actually submerging the gunwale, one has time to adjust oneself to the idea of living at an angle of forty-five degrees. During this process of heeling things slide—ballast, oars on deck, or anything unsecured. The contents of open cupboards are vomited across the cabin or galley in a highly projectile manner reminiscent of pyloric stenosis. Crockery and cutlery on the cabin table slide gracefully to the floor. The same applies to anyone who sits on the higher side of the boat, whereas those on the lower side find themselves pressed all too firmly into their seats. To stand upright or to walk about is a considerable muscular effort, and one stands erect at an apparently impossible angle which is very funny to watch. A ball thrown in the air describes a boomerang course. Meals are difficult to prepare and to consume: it is one thing to *feel* inclined to eat; to *be* inclined to eat is quite another matter. On the other hand, one can safely lay a table which looks like the side of a gable roof provided that it is cleared before the boat resumes its normal position as the tide rises.

* * *

It must be seven years since I made Lockyer's acquaintance at a performance of Handel's *Messiah* given in Southwark Cathedral. It was a dull afternoon without much promise; but a remarkable number of people assembled, and when the performance began every available square foot of floor-space appeared to be filled. Three girls had distributed themselves at various altitudes on the pulpit steps, while a few of the audience were sitting beneath the grand piano of the orchestra. I found myself occupying a flagstone in the North Transept, along with Lockyer and his Pills.

I wonder idly what colour they were, what (no doubt multifarious) ills of the flesh they were alleged to cure, and what great figures of the period swallowed them with scepticism or hope. It was, no doubt, a slip of the pen which led my fellow peripatetic to prune a word from the final couplet which should, I think, read:

> "This verse is lost; his PILL Embalmes him *safe*
> To future times without an Epitaph."

* * *

One of the gadgets with which our new operating-theatre was equipped came somewhere between a headphone and a loudspeaker. We did a lot of thoracoplasties under local anæsthetic, and it was felt that distraction might prove the better part of valour. The instrument was accordingly installed in the pillow of the operating-table and the patient offered the choice of Home Service or Light Programme—with a ban on items comical enough to affect the respiratory excursion.

The success of the experiment seemed assured when one patient announced that as the classical music came on he went to sleep "the same as at a concert." But a week later one of the patients undergoing thoracoplasty, who had been very still and quiet, suddenly started to groan pitifully; his pulse-rate and blood-pressure rose sharply. The explanation came later: he had dozed off, and the next thing that he knew was a choir of heavenly voices in the distance singing hymns, followed by a solemn voice referring to the Kingdom of Heaven. An aching body and the smell of the diathermy convinced him that he had gained admission to another world. It was some time before his premedicated mind realised that he was listening to a church service.

Shortly afterwards the headphone was sterilised by boiling by an enthusiastic junior member of the theatre staff. This seemed to upset it, and it was sent to the engineer with a label "Please Repair." That was ten months ago, and we haven't seen it since. We have not pursued the matter.

* * *

Last week, in search of toothpaste, I entered a large multiple store whose wares are conveniently displayed for all to see. Spring was evidently here, for the usual rainbow appearance of the toilet counter was transformed by an all-pervading green. The leading makers were offering their products combined with chlorophyll. Had their research laboratories proved that Nature's pigment was necessary for efficient oral hygiene? Was it in response to public demand? Had an enterprising representative of the Cabbage Growers' Association sold them the idea? As far as I was concerned the answer was simple. In a large family it is convenient for each member to use a tin or tube of differing appearance. There is now a fourth colour in the range of our favourite dentifrice, but I can still taste the peppermint.

* * *

News from the Ministry.—"But the Board would not have to apply for our approval before making . . . an upward adjustment in the half-days of an individual consultant or the appointment of an additional part-time cleaner." [B.G. 24/71/201.]

Notes and News

FACTORIES AND FOGS

AT the beginning of his visit to this country as a senior Fulbright fellow, Prof PHILIP DRINKER, of Harvard, gave a talk last Monday at the London School of Hygiene and Tropical Medicine

Though medical inspection of factories and mines began a century later in the United States than in Britain, "industrial hygiene as we know it" was, he said, an American product Usually the public health engineer was called in not by a doctor but by a management anxious to reduce its production costs, for in the U S A industries mostly ran at a profit or closed down Sometimes health risks were not considered at first, and litigation was the spur, but once managements were convinced that something must be done there was little difficulty in getting their coöperation The rôle of the physician in the appraisal of industrial disease could hardly be overemphasised, but Professor Drinker thought that prevention was the task of the public health engineer Statistics were not the exclusive property of the medical profession

Industrial hygienists in the U S A had been criticised, he continued for preparing official lists of the permissible concentrations of toxic substances It was said that knowledge was insufficient for the fixing of these figures But the first thing the public health engineer was asked was "how clean does this air have to be?" Where the contaminant was carbon tetrachloride or beryllium, for example it was no good answering "we'll follow the records and let you know in three years' time (or may be in fifteen years)" The engineer was used to working to a specification and must give a figure, even if it had to be revised later It was very rare in industry to abolish a poison completely after all, people put up with a certain amount of carbon monoxide from their cooking stoves and their cars But if it could not be reduced to a harmless concentration, or "dosage," at a cost the industry could pay, the process had to be given up

In conclusion Professor Drinker turned to the problem of contamination of the air not of factories but of whole cities In the U S A he said, they had fogs "just as thick and juicy as yours,' though these were quite different in Los Angeles, for example, from what they were in Pittsburgh But fog by itself was not a serious matter what made it dangerous was poisonous pollution The Meuse Valley fog had lasted four days, and had killed 64 persons, as well as many cattle In the Donora disaster there were 20 deaths with none in cattle The London fog last December, with its thousands of deaths, was a vastly different affair Moreover London had provided, for the first time, analyses of samples of air taken at the height of the fog It seemed surprising that the concentration of sulphur dioxide in the London fog reached only 1 3 parts per million, for in the U S.A 10 p p m was regarded as a permissible concentration for workers exposed for eight hours The deaths in London, however were mostly among invalids, infants, and "old people" (over 45!) In experiments in Professor Drinker's laboratory, respiratory reactions had been consistently evident in people breathing a mist containing very low concentrations of sulphuric acid which they could not detect Acetic acid was tolerated at high levels, but the effect of hydrochloric acid was somewhat similar to that of sulphuric acid Recently the experiments had been repeated with sulphur dioxide, and the investigators had been surprised to get a respiratory response in normal people at the very low level of 1 0 or 1 5 p p m The test had then been performed on furnacemen who were habituated to SO_2 concentrations as high as 20-25 p p m or even 30 p p m On exposure to concentrations of 5 p p m and 8 p p m these men showed no reactions whatever to them the mixture was apparently just the same as normal air

At the end of the lecture Dr ANDREW TOPPING, the dean, announced that Professor Drinker had been made an honorary member of the London School of Hygiene Association in token whereof he was presented with the club tie

SURGERY OF VARICOSE VEINS

A 16 mm silent film, dealing with this subject has been prepared under the medical direction of Mr R Rowden Foote Part I which runs for 18 minutes describes the stripping operation The Kodachrome colour is excellent and the film gives a clear exposition of the subject At the beginning there are rather a lot of subtitles, but the sequences of the actual operation are vivid and will convey to the student and general practitioner exactly what the operation involves Surgeons who are going to perform this operation will also find the demonstration helpful, although the introductory explanation, largely by subtitles, will be for them unnecessarily long The film is available on loan from Mr Rowden Foote, 137, Harley Street, London, W 1, who will give an introductory talk at medical society meetings to which the film may be shown

PROBLEMS OF CERTIFICATION

PAID sick leave undoubtedly encourages people to remain at home and nurse their ailments when otherwise they would struggle to work Often their temporary absence from work is, in the long run, a good thing[1], but the tendency to exploit indisposition can also be a bad one for all concerned The doctor is properly careful of the welfare of his patients, but overleniency will not necessarily serve them best, and the doctor who retains the confidence of the administrator is often the patient's best friend

In introducing the estimates of the ministry of labour and national insurance in the parliament of Northern Ireland on April 9, Major Ivan Neill said that the administrator sometimes feels that he does not always receive from the doctor the support he might reasonably expect Last year, he said, his ministry had to ask the ministry of health and local government for a second medical opinion on over 50,000 persons who were claiming sickness benefit Over 7000 of those called for examination did not attend and abandoned their claims, over 10,000 got a final certificate from their doctor, almost 12,000 of those who attended were considered fit for work by the medical referee The impression given by these figures was, he agreed, unduly gloomy, for some of those called for examination would of course have recovered before the examination

But Major Neill was disquieted by the records of some of the doctors "There are," he said, "very wide departures from the general average There are doctors who signed off more than 40% of those of their patients who were summoned for examination In other cases only 20% of the persons called for examination were considered by the referees to be incapable of work at the date of examination I am in consultation with my colleague, the minister of health and local government, about the action which should be taken to secure the necessary improvement in the standard of certification I have no doubt that only a small minority of doctors are at fault, but the fault is serious The acceptance of these certificates at their face value has led to payment of sickness benefit to persons who are not entitled to it, and we must get back to the position where full reliance can be placed on the doctor's certificate in every case I have no doubt that we shall have the support of the medical profession in any steps that may have to be taken "[2]

University of Oxford

The George Herbert Hunt travelling fellowship for 1953 has been awarded to Dr A C Allison, fellow of Exeter College

University of Cambridge

Dr F W Campbell has been appointed lecturer in physiology Dr C W McE Pratt and Dr J D Lever have been appointed demonstrators in anatomy, and Dr H B Barlow and Dr R H Winfield demonstrators in physiology

University of Glasgow

Prof E J Wayne has been appointed to the regius chair of practice of medicine in succession to Sir John McNee, who is retiring

Professor Wayne who is 50 years of age has been professor of pharmacology at Sheffield University since 1934 and professor of pharmacology and therapeutics there since 1942 He graduated B Sc in chemistry in 1921 at Leeds and was elected Sir Swire Smith fellow From 1924 to 1926 he undertook research in biochemistry in the University of Manchester and in 1925 he was awarded the degree of PH D Leeds in that subject In 1929 he graduated in medicine at the University of Leeds and served as demonstrator in physiology there before he was appointed assistant in the department of clinical research at University College Hospital London in 1931 He held this post till he moved to Sheffield in 1934 He was elected F R C P in 1937, and took his M D the following year His papers to medical and scientific journals have mainly dealt with [illegible] endocrinology and drug therapy

---

[1] See *Lancet*, Feb 28, 1953 p 428
[2] *Northern Ireland Parliamentary Debates* April 9, 19[illegible] [illegible]

The present legal procedure only allows a public trial for negligence by which an injured patient may try to recover financial compensation for his injury. Humanity dictates that such an injured patient deserves compensation, but I suggest that it is now time for a re-examination of the machinery for assessing claims for negligence in this matter. There are other injuries too, such as brachial-plexus palsy after long surgical operations, in which the possibility of accident may be present.

University College Hospital,
London, W.C.1.
R. W. COPE.

HOSPITAL COSTING

SIR,—It would be interesting to know upon what ground you state (March 28, p. 635) that "it is generally agreed . . . that there is no large-scale extravagance to be exposed, but only different degrees of housekeeping efficiency." So far as I am aware, no authoritative pronouncement has been made to this effect, and I doubt very much whether the Ministry of Health would accept it, since, apart from the decision to set up a committee of inquiry into the cost of the service, the latest memoranda on the control of hospital expenditure and manpower seem to imply—indeed more than imply—that considerable savings are possible.

Again, what is meant by "large-scale extravagance," and does the statement refer to individual hospitals or to hospitals as a whole? What figure have you in mind—£10,000, £20,000, or £30,000, or are you thinking of something in the region of £100,000? The spending of any sum of money by a hospital, no matter how small the amount, is extravagance if a commensurate return in service or goods is not received. It may well reach "large-scale extravagance" if it is repeated in thousands of hospitals all over the country. The estimated expenditure on the hospital service for 1953–54 is £269 million; so if only 5% of this amount were saved by improved methods of organisation and more efficient management, including cost accounting, the demand on public funds would be reduced by £13½ million. Hospital authorities have too readily accepted the "ceiling" laid down by successive Chancellors of the Exchequer as being the amount they should spend, and estimates are made accordingly.

You say that "because salaries are determined on a national basis, there is no point in elaborating the data. The most useful index to the adequacy of staff in any department is not financial: it is a statement of the number of people of different grades who are employed, related to equally simple numbers of patients, or tests, or examinations, or items of service." It may be agreed that this relationship is interesting, but it is certainly not the *most useful* if, indeed, it is useful at all. It relies upon the assumption that the adequacy of staff in any department can be tested by relating numbers of staff to the number of units of work. This plausible suggestion, which seems to offer a short cut to comparisons, fails in practice to detect anything but the grossest disparities in staffing; and if, as you begin by stating, these do not exist, then the method has nothing to commend it in any search for economy.

The most superficial examination of the suggestion shows that, far from being simple, it would soon lead to complications of the utmost intricacy. First, over what period is the number of staff to be calculated, and how is allowance to be made for comings and goings? What is the basis for part-time staff, necessarily ignoring that the cost thereof is proportionately greater? What are the "different grades" referred to, and how far should the differentiation be carried? For example: if one kitchen preparing (say) 1000 midday meals employs a catering officer, a head chef, a pastrycook, two assistant cooks, four kitchen assistants, two porters, and a part-time cleaner, under what system of barter is this to be compared with a kitchen preparing 800 midday meals, employing a head cook, two assistant cooks, five kitchenmaids, and two student nurses for special diets? Are differences in age, experience, and sex, each of which may affect cost, also to be ignored? In practical administration not only are all these factors influenced numerically, and in cost, by considerations of overtime, split duty, and shift-duty payments, but also any crude comparison of the sort suggested would be vitiated by differences in function carried out by "departments" of the same general purpose, one hospital with another. A common factor, understood by all, is required; and the obvious and relatively simple one of cost in terms of money has to be accounted for in any circumstances.

A third statement on which I should like to comment is: "There is a danger that the elaborate methods of costing that have served industry well will be too readily retained in the wholly different context of the hospital service." One may query the introduction of the word "elaborate." There are no doubt some industrial systems which may be considered elaborate, although they may not be so for the particular concerns, but most of them are reasonably simple. The fact to remember is that it is all too easy to instal a supposedly simple system only to find in practice that the simplicity is a myth and in any case is more than counterbalanced by incompleteness. One might argue that the present hospital costing system is simple; but it is extremely costly because it does not provide results which may be put to any useful purpose. An adequate costing system provides results which can be used.

Finally, what is meant by "different context of the hospital service"? In what material way is it different? It is true that hospitals treat patients and industry deals with inanimate "products," and to this extent there is a difference. But does this in itself dictate in any way the type of costing system to be introduced? I would say that it does not. Practically, both have to provide and maintain buildings; instal and maintain equipment, electrical, plumbing, and other services; employ and control staff; make purchases, store and issue supplies, and so on. There appears to be a mistaken idea that because hospitals treat patients business methods are not applicable; that they should be run on easy-going lines and only by those who have direct contact with the patients. If this reasoning is sound why bother about costing or even accounting at all; why bother about the number of staff, their grading, and the amount of work they perform? Why employ qualified administrators; why have committees and meetings? These and many other essentials come under the heading of "business methods." Such methods, which include adequate accounting on the lines proved effective in industry, are applicable in every way to the activities of hospitals—even more so as the cost is met from public funds.

No finance officer wishes to instal a costing system merely for the sake of doing so, but he does want to instal a system which will produce results which can be used by management.

ADMINISTRATOR.

*** On the question of large-scale extravagance we may quote the report of the Nuffield Provincial Hospitals Trust:

> "Dramatic economy will never be possible: there is no dramatic waste to be cured; it is only by eliminating every source of wastage and inefficiency and by making all within the service conscious of cost that the limited funds available for the hospitals will be spent in the best way."[1]

We did not mean to imply that there is no room for ordinary costing analysis in the hospital service; obviously there is, and our correspondent (quoting the situa-

Food-supplies, Population, and War

A conference on this subject will be held by the Medical Association for the Prevention of War at 2 P M on Saturday, May 2 at Church House, Westminster London, S W 1 The discussion will be opened by Dr Duncan Leys and Prof J B S Haldane, F R S The assistant secretary of the association is Dr Richard Doll, 24 Lansdowne Road, W 11

International Medical Congress

The third International Congress of Internal Medicine will be held in Stockholm from Sept 15 to 18, 1954, under the presidency of Prof Nanna Svartz The main subjects chosen for discussion are The Pathogenesis and Treatment of Hypertension and Mesenchymal Diseases (Collagenous Diseases)—their common characteristics and their nature The secretary general, Prof Anders Kristenson may be addressed at Karolinska Sjukhuset, Stockholm 60, Sweden

Child Health in the Tropics

A symposium on this subject is to be held in Jamaica from Oct 20 to 27, immediately after the International Pædiatric Congress (which takes place in Havana from Oct 12 to 17) The provisional agenda for the symposium includes the following sections nutrition, liver disease food poisoning in the tropics, infectious and parasitic diseases, prenatal and neonatal pediatrics, and organisation of child health work in underdeveloped areas Further information may be had from the secretaries of the symposium, Division of Medicine, University College of the West Indies, Jamaica, B W I

Industrial Diseases Committee

The Minister of National Insurance has set up a committee to review the present provisions of the Industrial Injuries Act under which benefit is paid for diseases and for personal injuries not caused by accident and to make recommendations Mr F W Beney, Q C, is to be the chairman, and the 11 members include Sir Ernest Rock Carling, Dr L G Norman, and Dr Alice Stewart

Centenary at Southampton

The Southampton Medical Society, under the presidency of Dr R S Swindell celebrated its centenary on April 18 Two hundred members and their guests were welcomed at the university by the vice chancellor Sir Russell Brain P R C P delivered an oration on Evolution in Medicine A dinner in the evening was attended by a hundred and forty members

The telephone number of Addenbrooke's Hospital Cambridge including the administrative offices of the board of governors of the United Cambridge Hospitals has been changed to Cambridge 5[illegible]71

A *Press guide to British Chemicals and their Manufacturers* has been published by the Association of British Chemical Manufacturers 166, Piccadilly London W 1

Nine consultants in tuberculosis from six overseas countries are taking part in a course arranged by the British Council in Birmingham and London from April 13 to 2[illegible] The course, which has been planned by Prof W H Wynn and Dr C H C Toussaint deals with British practice in the prevention and treatment of tuberculosis and with aftercare

both science and commerce. How often is it seen in this country?

If Sir Reginald Watson-Jones, as an orthopædic surgeon, is satisfied that enough is spent in this way on bacteriological research, there may be others who think otherwise; as "the last straw," their freedom of thought must be respected.

Department of Bacteriology,
St. George's Hospital Medical School. S. D. ELEK.

SITTING DOWN TO SURGERY

SIR,—What a ray of sunshine over Easter was Mr. Sacks's advocacy (April 4) of more sedentary surgery—taboo to all but orthopædic surgeons delving deeply in the palm. But let his team share equally in the general quest for peace and longevity.

His standing assistant must be tall and must peer precariously into the wound from the other side of the table. A short man mounted on a stool or platform would only add to the general instability. With deference, too, it would have been nice to have had a picture of Sister, mellifluent to the last, with her poor feet up.

London, S.W.3. C. I. MURPHIE.

TRICHOMONAS VAGINITIS

SIR,—The original article by Dr. Lanceley and Dr. McEntegart, the extremely interesting editorial, and the valuable letter from Mr. McCullagh in your issue of April 4 prompt me to make some comments.

In a series of cases of trichomonas vaginitis it was possible to find the organism in the prostatic smears from approximately one-quarter to one-third of all contacts tested. The method of testing by urethral scrapings has not yet been attempted, but it seems likely that Lanceley and McEntegart have rendered a real service by introducing this new way of finding the trichomonas in the male.

If gonorrhœa is a venereal disease, so is infestation with *Trichomonas vaginalis*. Of more than 500 patients with proved infestation seen by me in the last six years, only 2 were definitely virgins. Gonorrhœa, too, has on occasion been acquired by non-venereal channels. In a series of 1000 cases of vaginal discharge now being prepared for publication there were 103 cases of gonorrhœa, of which 2 were in virgins.

In cases of trichomonas vaginitis, with really efficient treatment of the vaginal discharge, including if necessary the treatment of trichomonas cystitis, the disease will not relapse if intercourse is eschewed. It will often, however, recur if intercourse without a sheath is allowed.

I have seen severe trichomonas vaginitis with remissions and relapses after several months in a patient whose symptoms began shortly after a repair operation. The remissions followed treatment with acetarsol pessaries; the relapses followed intercourse. Similarly another patient dated her vaginitis from a visit to a practitioner who fitted her for a Dutch cap. Gonorrhœa can be transmitted by rubber gloves as can syphilis or trichomonas. Possibly all three can also be transmitted by lavatory seats, and it is surely reasonable that the U-type seats advocated by Mr. McCullagh should be installed at least in the lavatory in every gynæcological ward.

Commonly, doctors in venereal-disease and gynæcological clinics wear the same pair of rubber gloves for the whole session, merely washing the hands with soap and water between cases. Soap and water will kill most organisms, but detergents are extremely effective trichomonicides. I therefore urge that the gloved hands be dipped into a bowl of detergent before being dried after washing. Detergents should, however, be used with the greatest of care in vaginal douches, and never in bladder washouts, for severe reactions may occur.

London, W.1. ELLIOT E. PHILIPP.

EXTRAORDINARY MEETING OF THE B.M.A.

SIR,—I note that, following the requisition for an extraordinary general meeting of the British Medical Association, the Working Party has been called together in order to take effective steps to investigate and relieve any injustice inherent in the distribution plan. This belated action does in fact secure the main purpose of the requisitionists, for it is accompanied by an assurance that any injustices which are found to exist will be made good retrospectively to April 1, 1953. It therefore appears to me that it is no longer necessary to ask that the implementation of the scheme should be postponed pending a proper inquiry, and I have accordingly submitted an amendment as follows: "To delete all the words following the words 'entry into practice.'" I trust this will be acceptable to the requisitionists, the proposed amended resolution being:

> "That the Association being concerned by the modification of the present method of remuneration by capitation fees agreed in the Working Party's Report requires the Council forthwith to approach the Minister of Health with proposals for the better protection (financial and otherwise) of the small-list doctor and of the doctor newly seeking entry into practice."

May I trespass on your space to add a personal reflection? The Working Party should have taken effective action to inform itself of the nature and size of the problem and to devise a suitable solution not later than last October; had it done so, small-list practitioners and others would have been spared much anxiety and distress, and there would not now be this need for the requisitioning of an extraordinary meeting.

London, W.1. HORDER.

KERNICTERUS

SIR,—Although we are not in a position to comment on the histological evidence of identity of the various forms of kernicterus, we would like to make some observations on the conclusions that Dr. Govan and Dr. Scott draw from their observations (March 28).

They state that anoxia of the brain is the primary mechanism and that the pigmentation is secondary. If this anoxia is regarded as occurring at birth it is difficult to explain the lesions produced in young animals by Eyquem.[1] Here the blood incompatibility was induced postnatally. Further, if the anoxia is regarded as secondary to anæmia it is difficult to explain the development of kernicterus in human infants with comparatively slight anæmia but deep jaundice. This phenomenon is well known to clinical observers and is confirmed by Mollison and Cutbush.[2]

Crigler and Najjar[3] reported a familial type of non-hæmolytic jaundice in which kernicterus was a feature in 5 out of 6 infants. It is difficult to attribute this to anything other than an underlying disorder of liver function of which abnormal pigment metabolism was the outward sign, if not the responsible agent. The direct association between abnormal pigment metabolism and kernicterus has been made clear by Mollison and Cutbush[4] and Diamond et al.,[5] high serum-bilirubin concentrations in the neonatal period being associated with the development of kernicterus. One of us has recently made observations on the antenatal prediction of hæmolytic disease of the newborn[6]; these have shown that the development of kernicterus is directly related to the pigmentation of the liquor amnii and that this pigment is possibly derived from abnormal breakdown of hæmoglobin.

muscles (with their nervous connections), and they may appear to be mentally retarded because their disability has deprived them not only of opportunities for gaining experience of their environment, but also of satisfaction of the instinct to explore And so their conduct or behaviour may lag behind their age

Human Contacts

As yet I have referred only to the physical or material things in a child's environment—the lights and coloured toys, the sounds of rattles, the touch of the mother's breast upon the child's lips These contacts give him experience, provided that he is equipped to make use of them, and with this experience his behaviour develops in a normal, though stereotyped, fashion But it is doubtful whether it influences the conduct of a healthy child in later life, except in a very general sense On the other hand, a child's contacts with human beings *as individuals*, each with a different pattern of behaviour, bring into the picture relationships that make a much more significant and complex impact upon his conduct, both in childhood and in later life

When we try to analyse these intimate relationships we find that most children show at least three marked characteristics—namely, their tendency to imitate, their capacity for hero-worship, and their power of imagination The instinct to imitate is fundamentally protective, and we can well imagine that the infantile death-rate in the animal world would be infinitely greater if the young did not follow closely the pattern of life set by their parents In man mimicry has become less obviously protective in function, though still important because the child is likely to imitate the patterns of behaviour presented to him, whether or not they are desirable from social and ethical points of view Certainly the ability of a child to copy a person's conduct, as distinct from separate physical attributes like quality of voice and gestures, depends largely upon his understanding, and thus the gods and goddesses of one's childhood are more likely to be teddy bears, cricketers, footballers, and ballet-dancers than the types of whom Carlyle wrote, such as prophets and poets

Limits of Understanding

I mention this obvious fact to indicate how often the behaviour of children becomes unnatural and sometimes objectionable when the very limited range of their understanding is not appreciated by those about them It is the reason why, in my view, the well meant endeavours of many parents in the first half of the 19th century to foster their children's spiritual development fell so short of their hopes, and not infrequently resulted in bewilderment, priggishness, and sometimes abject terror You have only to dip into Mrs Sherwood's remarkable book *The History of the Fairchild Family* (1818, 1842, and 1847) to get an impression of the very abnormal effects that might be induced in this way

I will quote only one illustration—the incident when Mr Fairchild found his three children squabbling over a doll After dinner he said to his wife 'I will take the children this evening to Blackwood and show them something there which I think they will remember as long as they live, and I hope they will take warning from it and pray more earnestly for new hearts So he took them to Blackwood and there was a gibbet on which the body of a man hung in chains The body had not yet fallen to pieces although it had hung there some years It had on a blue coat a silk handkerchief round the neck with shoes and stockings and every other part of the dress still entire but the face of the corpse was so shocking that the children could not look upon it There Mr Fairchild made the children sit while he told them the tale of the murderer who had first hated and afterwards killed his brother

Or you may turn to a more gentle illustration, to the *Hymns for Infant Minds* (1811) by Jane and Ann Taylor, who also wrote the famous "Twinkle twinkle little star," and hear in imagination the high pitched tremulous voices singing

I thank the goodness and the grace
Which on my birth have smiled,
And made me, in these Christian days
A happy English child

I cannot lay me down to rest
In quiet on my bed
Until with shame I have confessed
The naughty things I said

Yet the authors, in their preface to these Hymns declared that their intention had been to adapt "Evangelical truths to the wants and feelings of childhood, in language that it understands" As we all know, and as Francis Thompson illustrated so beautifully in his essay on Shelley, it is difficult for an adult to go down to the level of a child's intelligence without making a complete fool of himself—"Know you what it is to be a child?" asked Thompson

"It is to be something very different from the man of today it is to be so little that the elves can reach to whisper in your ear it is to turn pumpkins into coaches, and mice into horses, lowness into loftiness and nothing into everything it is to live in a nutshell and count yourself the king of infinite space "

Imagination

These words are a reminder, too, that children often spend a part of their days in a state of imagination or fantasy, an almost limitless world of make believe which brings them great happiness and fosters many attractive qualities as well as the beginnings of a reverence for Nature I knew a little girl, an only child, who had nine imaginary brothers and sisters—her parents confirmed to me with an obvious feeling of relief that they *were* imaginary !—and she knew not only their names and ages, but what they were all doing from hour to hour, the names of their dolls and dogs and cats, and all about them They were, so to speak, in the direct succession to Alice and John, the dream children of Charles Lamb's reverie, and they provided an outlet for her sympathy and affection

Friedrich Froebel (1782–1852), the founder of the kindergarten system of education, was another who in his childhood was deeply moved by fantasy, especially in the world of plants and flowers He had been neglected and misunderstood, and in his autobiography he says, "Early was I plunged into the painful and oppressive struggle of life" Being brought up in a hard school his fear of punishment sometimes caused him to tell untruths, and to be accused of being a wicked little boy, with the result that his sensitive nature, given to introspection and self analysis, suffered cruelly At the age of 15 he was apprenticed to a forester, and as one who, in his own words, "loved mountains, fields and forests" he developed a religious communion with Nature From this there sprang the conviction, basic to his scheme of education, that man is in essential unity with all things especially with Nature, and that the teacher's chief job is to provide a suitable environment in which the child's faculties may unfold To perpetuate this idea he coined the term "kindergarten" for the first of his schools

Froebel was a vigorous thinker whose contribution to education was considerable and he did much to establish the importance in a person's development of the early years of life The history of his own life illustrates how strongly fantasy in childhood may play a part in leading to significant activities in adult life, for children have still another instinct, what George Sampson called the creative instinct and it is closely allied to their power of imagination In amplifying this theory, Sampson wrote of a common mistake that is made in the upbringing and instruction of children—the mistake of believing that a child is a miniature adult and therefore capable of very extensive resection (leaving 1 × 3 in.), but at the time of his death we had not established the optimum. Even though we have now followed up all his patients for at least four years, it is still unwise to endeavour to define this, as the incidence of symptoms is influenced by so many other factors.

It is difficult to translate clinical results into figures, and I must apologise if my very factual report has given the impression that the results were unsatisfactory. A more human and possibly more accurate assessment has been made by these patients, who, on their own initiative, combined to endow two memorial prizes for nurses. As the amount subscribed exceeded requirements, they have obtained the sanction of the Chapter of York Minster—no easy matter—to erect a panel depicting the Art of Healing through the ages, and incorporating the name of Arthur Visick. This, I understand from the Dean of York, will be the first of its type in any cathedral in the country.

York County Hospital. C. N. PULVERTAFT.

WATER DIURESIS TEST

SIR,—Dr. Oleesky (April 18) proposes a "specific" water diuresis test for adrenocortical insufficiency, which should be a useful simplication of the Robinson-Power-Kepler procedure.

Unfortunately, false negatives are not eliminated by this modification. We have recently studied two undoubted cases of Addison's disease, both of which showed no eosinophil or ketosteroid response to 8-hour infusions of 20 mg. of A.C.T.H. in saline, on two successive days. In each case the maximum rate of urine flow after ingestion of a litre of water exceeded 10 ml. per minute without cortisone. The only *specific* test for adrenocortical insufficiency is the 2-day intravenous A.C.T.H. test, described by Renold et al.[1]

Medical Unit,
Royal Infirmary,
Cardiff. T. M. CHALMERS.

ENDEMIC GOITRE

SIR,—It would indeed be unfortunate if, at a time when new techniques of great value are emphasising the importance of the thyroid hormone in human metabolism, readers of your annotation (April 11) were left with the impression that "most goitres are quite harmless"—an observation which Dr. Stanbury himself did not make. Observations in North India and Nigeria as well as in rural Oxfordshire[2] have also shown that gross thyroid enlargement may have serious economic as well as physical consequences.

The recent introduction of a new grade of fine vacuum salt—dendritic salt—which lends itself to iodisation and can be supplied at a lower cost than coarse uniodised salt for districts where the amount of local salt is inadequate, should go a long way to meet your query as to "whether iodine prophylaxis is worth the effort and expense."

Oxford. DAGMAR WILSON.

AUGMENTING KNEE-JERKS

SIR,—Of all the tricks and artifices employed by doctors to elicit physical signs, few appear more ludicrous and more difficult to follow than the means of augmenting sluggish knee-reflexes.

One asks the patients to clasp their hands and pull, to clench the jaw (or gnash the teeth), to close the eyes or to look at the ceiling and pretend that the doctor does not exist; and to ask any patient to "relax" at once becomes the signal for the body to stiffen into a catatonic state with the legs rigidly extended into the air. What with coaching, coaxing, and correcting, the doctor has often forgotten at the end of it just why he wanted to test the reflexes anyway.

I have found that all these devices may be dispensed with and replaced by a simple manœuvre. With the patient recumbent, lift both knees about nine inches and ask the patient to push both heels gently on to the bed. This contracts the antagonists and automatically relaxes the extensors to be tested. In addition it always augments the knee-reflexes and rarely excites ribald laughter or a gnashing of teeth.

Central Middlesex Hospital,
London, N.W.10. B. I. HIRSCHOWITZ.

UTERINE CANCER AND VAGINAL SMEARS

SIR,—With reference to the remarks in your leading article last week, for the past four years I have been examining the breasts of all patients referred to me for a gynæcological opinion. At the same time the possibility of carcinoma of the rectum has always been remembered when carrying out pelvic examinations. I have discovered four carcinomas of the breast and one carcinoma of the rectum.

The patients with carcinoma of the breast were referred because of: (1) a pelvic-floor prolapse, (2) slight intermenstrual bleeding (a small cervical polyp was discovered), (3) an enormous ovarian cyst which filled the abdomen, and (4) irregular vaginal bleeding which was found to be due to carcinoma corpus uteri (this patient had a double primary carcinoma).

NORMAN KIMBELL
Consultant obstetrician and gynæcologist,
Peterborough area.

PROFESSIONALISM IN THE HEALTH SERVICE

SIR,—The certitudes of the maiden aunt as to how her married sisters should—but do not—nourish and rear their children are known to most parents, but much is forgiven to this well-meaning lady because she has her own virtues. Yet even the most patient of harassed mothers will sometimes ask herself whence the source of the superior wisdom so firmly pressed upon her, and by what right it is proffered.

If he will forgive me for saying so, Mr. Farrer-Brown has constituted himself the most censorious of doctors' maiden aunts in his address to the Institute of Almoners, published in your issue of April 11; but unlike his prototype he has not addressed himself to the persons directly concerned, but publicly to another audience; one that is not responsible for the shortcomings he detects in us, nor able to do anything about them.

I do not seek to fathom why he should have approached us on his delicate mission in this very indirect and public fashion—so that we are the last to hear what he has to communicate—nor to deal with his severe strictures upon those of us who (as he believes) show "consistent incompetence and persistent neglect" in our work. We are too used to the curtain lecture to be unduly sensitive to this latest and most drearily humourless of its many versions.

Yet I do feel that his hazy notions as to what constitutes a profession may usefully be considered, for upon this question are based our relations with the diverse ancillary services that we now have at our disposal in the practice of medicine.

He says that "in so many respects there seems no apparent distinction between a vocation which is generally recognised as a profession and one which is not . . . There seems to be one distinctive feature which is at the heart of the question . . . It concerns the nature of the relations between the professional man or woman and the individual he is engaged to serve." This relation, he goes on to say, is that of trust. But is there any avocation that may bring a man into business or contractual relationship with customer, client, employer, or employé where there does not exist this relationship? Only Robinson Crusoe on his island before the advent of man employment under harsh conditions. It seems probable that childhood delinquency, in our sense of the word, was less widespread than it is today, partly because there was little time available to them to get into mischief, and partly because they were habituated to a stern discipline in the home—sometimes, it is true, a crude form of discipline, and perhaps misguided because the level of general education was so low, but none the less effective because it was repressive. And not infrequently parental control was backed up by threats of divine sanctions, for the doctrine of original sin was fairly widely accepted. There is plenty of evidence that many of the survivors of that epoch, covering the first fifty years of the 19th century, looked back upon their childhood with bitterness.

---

[1] Renold, A. E., Garcia-Reyes, J., Jenkins, D. *J. clin. Invest.* 1952, 31, 657.
[2] Medical Research Council memorandum, no. 18. H.M. Stationery Office, 1948.

It is not easy to get a clear picture of what is happening in the minds of children living in corresponding circumstances today. Their parents are better educated, but many are still ignorant and feckless, their housing conditions are lamentable, and there is fairly general agreement that moral and ethical standards are low. It would be surprising if many children brought up under these conditions did not show some undesirable effects in their behaviour, yet we must be cautious in coming to conclusions about the incidence of such effects, because our newspapers see to it that we hear all about the delinquents, and little about the others, and similarly it is the children who steal our flowers and fruit, who scratch our cars, and break our street lamps, that give us reason for remembering them. The wartime evacuation of city children to districts less likely to be bombed was, in one sense, a great social experiment that brought to light many personal shortcomings and social evils, and the report entitled *Our Towns: a Close-Up* by the hygiene committee of the Women's Group on Public Welfare horrified the country by its revelations. Above everything else it revealed the terrible effects of the adult "slum mind" upon children—effects due mainly to ignorance of the care and upbringing of children and of general household management, wrong ideas about the best use of money, evasion or negligence of the duty to instil discipline, and often a sad failure by the adults to set an example of decent, honest living. The children are now back in the cities again, and the public conscience has lulled itself once more into a state of apathy.

It is interesting to look again at the conclusions reached by informed opinion at the time that *Our Towns* and other similar reports were published and to note how much faith was then placed in extending the policy of granting more material assistance, drawn from the national Exchequer, to more families. It must, of course, be admitted that such assistance, in one form or another, is essential for a great many families, if we, as a nation, are intent upon maintaining our reputation for taking care of the needy, our chief problem is to ensure that the help given to parents is educational as well as material. This point has not yet received the attention that it deserves. The homes of the people should be places fit for children to live in, and it is an evasion of the issue to argue that, as an alternative, the younger children should attend nursery schools, and similar places, where they will be taught to keep themselves clean and where they will find a satisfactory diet and opportunities for sound sleep beyond the range of the wireless. As a temporary expedient this might be reasonable, though very expensive, but at a time when the god of planning ranks as deity no. 1 let us first be sure that our aims are fundamentally sound. Do we honestly believe that the home, and all that it stands for as the focus of family life, is worth preserving, or do we think that it can be profitably replaced by schools, centralised restaurants, and other institutions, no matter how well these may be planned and administered?

Excessive Solicitude

You will, I think, have sensed one outstanding difference between the two large groups of children I have been considering, our concern for the less fortunate group—the children of the social class that used to be called the poor—is that we should use all practical means at least to raise them from frank inferiority, while for the more fortunate children, relatively safe from the threats of the five giant evils, and already enjoying a good standard of living, we have opportunities for striving more closely to the ideals we hold. Let me revert, therefore, to the children in our own social group and see whether I can summarise the thoughts which are the basis of this address.

The younger they are, the more their conduct is a measure of their physical endowment and growth, and this "bodily" phase, if I may so call it, has a significance and importance beyond all comparison with physical activity in adult life because the child is actively growing and the full evolution of his behaviour is dependent upon a satisfactory start. Then comes the phase in which relationship with other persons dominates the picture. We have seen that, as a background, good hygiene, exemplified by satisfactory housing conditions, suitable diet, opportunities for sleep and recreation, cleanliness, and so forth is of much importance, and that certain intangible requirements, especially security in the home, discipline, and good example, are perhaps even more important if conduct in childhood is to develop later into sound citizenship. But I do not want to end this address on too austere a note. Childhood should be a period of happiness and we adults must be careful not to smother their spark of gaiety under a mound of excessive solicitude and anxiety for perfection. And as an added warning against over-concern for the young, remember that the "heavy" father—or "heavy" mother, for that matter—may sometimes have to suffer the double annoyance of failing to achieve his object and of making himself appear ridiculous.

> "Auntie, did you feel no pain
> Falling from that apple tree?
> Would you do it, please, again
> 'Cos my friend here didn't see."
>
> *Ruthless Rhymes* (CAPTAIN GRAHAM)

Potentialities

Children are all different and no two sets of circumstances are alike, each must be an individual study. Nor do I feel that I should attempt to answer the interesting general questions that I mentioned earlier, because in human affairs rules are usually found to have too many exceptions. In slum districts, for instance, you will find thousands of families leading exemplary lives despite the most forbidding handicaps, and among "educated" people you will find examples of abnormal childhood behaviour because education has been assumed like a veneer, and has not been absorbed into life as a basis of character. Furthermore, some of those people who have later made noteworthy contributions to life whether in literature, science, the arts, or what you will, have been very strange and difficult children. Shelley, shy and meditative, was at heart a rebel and at times of provocation could be dangerously pugnacious, Keats, though superficially carefree was oppressed by a strange sense of melancholy, John Hunter, the famous surgeon, found much difficulty in learning even the rudiments of reading and writing at the age of ten, and Latin had to be abandoned.

If one leaves out of count those children that have followed an entirely unexpected course in their subsequent development and behaviour, there are good grounds for maintaining that the qualities most sought after because, in our phraseology, they are most civilised are established in the years of childhood, an adventurous, courageous, but disciplined spirit, a character

He was born in London and he studied medicine at St. Bartholomew's Hospital and the University of Durham, where he graduated M.B. with first-class honours in 1887. Two years later he was awarded the gold medal for his M.D. thesis on colour-blindness, in which he attacked the Holmgren wool test and first put forward his theories on the function of the retinal rods and of the visual purple.

Soon afterwards his views received wider publicity when Sir Lauder Brunton presented a paper of his to the Royal Society, and he was appointed a member of the International Code of Signals Committee. But his views did not win immediate acceptance: and in 1892 a committee of the Royal Society unanimously recommended the continued use of the Holmgren test to railway companies and shipowners. Though disappointed by this setback Dr. Edridge-Green published a further monograph on his work, and in 1904 a committee of the Ophthalmological Society confirmed his contention that some cases of colour-blindness cannot be detected by the Holmgren test. Fortified by this support he went to Cambridge at his own expense to obtain further evidence. There, however, he was coolly received and his thesis was turned down. But he continued to press his case, and in 1909 he published a monograph on *Colour Blindness and Colour Perception*. Meanwhile at Oxford Doyne and Gotch had confirmed his findings, and gradually informed opinion turned in his favour.

In 1911 he delivered a Hunterian lecture on colour-blindness at the Royal College of Surgeons, and the following year a committee of the British Association reported in his favour. Questions were asked in Parliament, and in 1915 the wool test was abandoned by the Board of Trade and a lantern based on Edridge-Green's principles was adopted. Five years later he was appointed an adviser to the board. In 1920 he was appointed C.B.E., and the same year he gave the Arris and Gale lectures at the Royal College of Surgeons. In 1930 he was president of honour at the annual meeting of the Ophthalmological Society of Paris, and in 1936 he was awarded the Thomas Grey prize.

Dr. Edridge-Green's own account of these far-away battles, which he published in 1933 under the title of *Science and Pseudo Science*, shows him to have been a trenchant and contentious controversialist, and much of his work on the physiology of vision is at variance with present-day thought. But personal difficulties and scientific differences cannot obscure his real contribution to the safety of transport on land and sea.

In 1893 he married Minnie Jane, the daughter of Dr. Henry Hicks, F.R.S. She died in 1901 and there were no children of the marriage.

ALEXANDER MITCHELL

M.A., Ch.M. Aberd.

Mr. Alexander Mitchell, consulting orthopædic surgeon to the Aberdeen Royal Infirmary, died on April 16, at the age of 72. The record of his family's connections with medical practice is impressive. His grandfather and father practised at Old Rayne, Aberdeenshire, his two brothers were doctors, and one of his sons is Major Patrick Mitchell, R.A.M.C. His first wife was a daughter of the late Dr. Greig of Fyvie, and his second wife a daughter of the late Dr. David Rorie, whose poems, including "The Lum Hat Wantin' the Croon," are well known in the North of Scotland and far beyond.

He graduated M.A. at Aberdeen University in 1901, M.B. in 1905, and CH.M. in 1907. He spent several years in general practice with appointments at Fyvie Hospital and Gray's Hospital, Elgin, but his career in surgery began about 1914 when he was appointed to the Royal Hospital for Sick Children and the Royal Infirmary, Aberdeen. Himself crippled, he had a strong bent for orthopædics which was stimulated by his surgical experience at base hospitals in Rouen during the 1914–18 war and later became his main professional interest. Between the wars he developed an orthopædic department at Aberdeen Royal Infirmary and later, with the help of the Cripples' Welfare Association, an orthopædic service for the whole North East of Scotland. During the late war he became orthopædic consultant to the E.M.S. and the Army Medical Services in the North of Scotland. Undeterred by a first attack of coronary thrombosis in 1942 he carried a heavy burden of work during the war years and, even after retirement from his Aberdeen hospital appointments in 1945, he continued as consultant to the Department of Health and to the North-Eastern Regional Hospital Board under the National Health Service. He was also a vice-president of the Orthopædic Association. Recently he became chairman of the management board of the Aberdeen special hospitals group and, in fact, was presiding at a board meeting when the final coronary attack began.

W. C. W. *writes*: "Distinguished as were his services to orthopædics. Sandy (as he was known to all) will best be remembered for his personal qualities and relations with patients. More interested in men than in affairs, he had a fund of reminiscences and stories and a dry, sardonic wit which made him excellent company. His opinions and judgments were forthright and decided, but always fair and often generous. He had a delightful manner with sick children and a real sympathy for the deformed and maimed. His own standard of service to patients was the highest and he demanded the same from his juniors. In this one could see the influence of tradition and upbringing in a medical family and it is a safe assumption that the tradition has been handed on to many former assistants and students. As usually happens, they were quick to see the sterling qualities of the man and with them his popularity was high. His character has been summed up in the words of an old patient: 'He was a grand gentleman, Sandy Mitchell.'"

Mr. Mitchell is survived by two sons and a daughter and by his widow who gave him great help in his last years.

Births, Marriages, and Deaths

BIRTHS

FORBES.—On April 15, to Pamela, wife of John Forbes, M.D., of Pen-y-wern, near Mold, Flintshire—a son.

FOXELL.—On April 13, at Suffolk House Nursing Home, Stanmore, to Maureen, wife of Dr. Alan Foxell—a son.

MARRIAGES

NEWBORNE—SKELTON.—On April 18, at St. Giles Church, Oxford, Laurence Perceval Anthony Newborne, M.D. Lond., to Mary Skelton, M.C.S.P.

Appointments

BICKFORD, J. A. R., M.R.C.S., D.P.M.: consultant psychiatrist, De la Pole Hospital, Willerby, E. Yorks.

DAVIES, E. B., M.B. Manc.: medical registrar, Rookwood Hospital, Cardiff.

HILL, J. N., M.B. Leeds, D.P.H.: medical director (S.H.M.O.), Leeds mass-radiography unit.

MORTON, J. A., M.B. Edin., M.R.C.P.E.: M.O. (part-time), H.M. Prison, Edinburgh.

TODD, ELIZA, M.B. Aberd., D.P.H.: asst. M.O., Heston, Isleworth, Southall, Brentford, and Chiswick area, Middlesex County Council.

VICKERY, K. O. A., M.D. Lond., D.P.H.: M.O.H. and school M.O., Eastbourne.

Colonial Service:

ALLEN, C. P., M.B., CH.M. Glasg., F.R.C.S.E., D.T.M. & H.: specialist officer, grade A, Federation of Malaya.

COCHEMÉ, M. A. X., M.B. Camb., D.T.M. & H., D.P.M.: specialist officer, grade A, Federation of Malaya.

DRURY, GRAHAM, M.R.C.S., D.T.M. & H., D.A.: A.D.M.S., Kenya.

EDDEY, L. G., M.B. Aberd., D.T.M. & H.: D.M.S., Gold Coast.

FRANKLIN, G. C., M.B. Camb.: M.O., Hong-Kong.

GREEN, R. T. B., M.D., D.T.M.: Specialist officer, grade A, Federation of Malaya.

MOLESWORTH, B. D., M.B. Camb.: specialist officer, grade A, Federation of Malaya.

PALLISTER, R. A., O.B.E., M.D. Durh., M.R.C.P., D.T.M. & H.: specialist officer, grade A, Federation of Malaya.

RYAN, J. C., M.B. N.U.I.: M.O., British Guiana.

SHAW, R. E., M.B. Lond., F.R.C.S.: M.O., Kenya.

SINCLAIR, WILLIAM, M.B. Belf.: M.O., Nyasaland.

Western Regional Hospital Board, Scotland:

CUTHBERT, RICHARD, M.B. Glasg., D.M.R.D.: asst. radiologist (S.H.M.O.), Stirling county area.

HARPER, JAMES, M.B.E., M.B. Edin., M.R.C.P.E., D.P.M.: consultant psychiatrist and deputy physician-superintendent, Crichton Royal Mental Hospital, Dumfries.

TAIT, A. C., M.B. Glasg., D.P.H., D.P.M.: consultant psychiatrist, Crichton Royal Mental Hospital, Dumfries.

TABLE II—CHOLINESTERASE

(µl carbon dioxide per g per hr)

Tumour no	Substrate		
	Acetylcholine	Acetyl β methylcholine	Butyrylcholine
1	6380	1265	8100
2	950	221	1170
3	434	133	27
4	630	34	621
5	1015	292	988
6	1130	636	109
7 (a) Pure	—	—	—
(b) Edge	1020	65	712
(c) Centre	2580	1160	1830
8	2010	1130	1740
9	4830	2060	793
10	784	—	—
11	147	41	319
12	0	0	25
Cortex adjacent to abscess	898	470	733

glioma obtained from the child that the content in pressor amines, particularly noradrenaline, far exceeded that in all the other tumours The amine oxidase content was also high, but not outside the range of that in several other tumours Cholinesterase activity, especially the non specific or pseudocholinesterase, as shown when butyrylcholine was used as a substrate, was also very high in tumour no 1 The values for amine oxidase in gliomas varied over a wide range they exceeded the amounts found in the meningiomas and in most cases there was also more cholinesterase How difficult it is however, to obtain a definite correlation between cell type and enzyme activity is shown by tumour no 7, of which three different portions were investigated The sample of the astrocytomatous part of the tumour was too small to permit estimation of more than the amine oxidase The part of the tumour which was infiltrating the brain showed more amine-oxidase activity than did a portion taken from the centre, whereas the cholinesterase activity was higher in the centre of the tumour than in the peripheral portion An ependymoma of the spinal cord (tumour no 8) resembled most of the gliomas in its enzyme content as well as in its content of pressor amines This finding was interesting because the ependymomas are usually classified histologically with gliomas A neurofibroma of the acoustic nerve (tumour no 9) contained very low amine oxidase activity but very high cholinesterase activity, especially the specific or true cholinesterase, as shown when acetyl-β methylcholine was used as a substrate In two meningiomas no amine oxidase activity could be estimated, and in the third it was the lowest value found Similarly, the cholinesterase content was very low in the three meningiomas (tumour nos 10 11 and 12)

The question asked at the outset—whether neuroglia contains enzymes concerned with the metabolism of nervous transmitter substances—has been answered in the affirmative For comparison with the activity found in the brain tumours the values found in one specimen of human cortex from the right temporal region adjacent to an abscess removed at operation are given at the end of tables I and II In addition we are greatly indebted to Prof R H S Thompson and Dr A Tickner for their permission to cite results obtained on areas of the human brain shown in table III These values agree fairly well with those published by Birkhäuser (1940) on human brain cortex, when recalculated and expressed in the same terms, though the activity found by Birkhäuser in the thalamus and caudate nucleus was higher

TABLE III—AMINE OXIDASE ACTIVITY OF HOMOGENATES OF HUMAN BRAIN

(R H S Thompson and A Tickner, unpublished)

Area	µl oxygen per g per hr (in presence of cyanide)
Cerebral cortex grey matter	20[illegible]
Frontal	228
Parietal	170
Temporal	127
Occipital	
Cerebral subcortex white matter	1[illegible]1
Frontal	112
Parietal	27[illegible]
Internal capsule	[illegible]
Red nucleus	1[illegible]4
Corpus callosum	132
Cerebellum (grey)	1[illegible]7
(white)	

The amine oxidase activity which we found in glia tumours (table I, nos 1–8) falls within the range of that in various parts of the brain (table III), but the activity of the meningiomas (table I, nos 10–12) is well below

Perhaps the presence of pressor amines, particularly noradrenaline, in some of the tumours is even more significant than that of amine oxidase, which has a far wider distribution in the body Vogt (1952a and b) found 1–2 µg of noradrenaline per g of fresh tissue in cat's hypothalamus and about 1 µg per g in dog's hypothalamus, parts of the mid brain and medulla containing 25–30% of these figures Adrenaline, when present, was found in quantities of only a tenth of those of noradrenaline Tumour no 1 contained more pressor amines than did any of the areas investigated by Vogt (1952a and b) The amounts found in nos 2 and 3 are close to normal figures in dog's thalamus A sample of human cortex adjacent to an abscess contained none

In eight samples of brain tumours (table II, nos 1, 2, 5, 6, 7b and c, 8, 9) cholinesterase activity was found to be very high and of the order reported by Ord and Thompson (1952) for substantia nigra, cerebellum, thalamus, and red nucleus But, whereas in these areas the activity was mainly due to true cholinesterase, in six tumours histologically classified as gliomas, the pseudocholinesterase activity was very much higher than that of true cholinesterase This is interesting in view of the suggestion of Ord and Thompson that the function of pseudocholinesterase may be connected with processes in neuroglial elements Tumour no 1 contained more pseudocholinesterase than did any normal human brain area investigated by Ord and Thompson On the other hand, tumour no 9 with high total activity (a neuroma arising from the acoustic nerve) contained the greatest amount of true cholinesterase of all

SUMMARY

Glia tumours made up predominantly by glia cells may contain as much enzyme activity as normal brain tissue in which glia constitutes only a fraction of the different cell components Amine oxidase activity was of the same order as that in normal brain areas

Cholinesterase activity in six out of eight gliomas was greater than in normal cerebrum (grey and white) and of the order found in the thalamus, mid-brain, and cerebellum, but, in contrast to these, it was mostly due to pseudocholinesterase

One glioma (in a child) contained a larger amount of noradrenaline than has yet been found in any area of the normal central nervous system

We are greatly indebted to the late Sir Hugh Cairns and to Mr Joe Pennybacker for providing the material obtained at operations

University of London

Dr. Miles Weatherall, senior lecturer in pharmacology at London Hospital Medical College, has been appointed to the readership in pharmacology at the college. Mr. L. F. Lamerton, PH.D., senior assistant physicist at the Royal Cancer Hospital, has been appointed to the readership in physics applied to medicine at the Institute of Cancer Research at the hospital.

University of Birmingham

Dr. Edwards A. Park, emeritus professor of pædiatrics in Johns Hopkins University, will deliver the Leonard Parsons lectures at the university on Tuesday and Wednesday, May 5 and 6, at 4 P.M. The subject of the first lecture is to be the Effects of Severe Infection and of Malnutrition on Normal Bone Growth and their Influence on Rickets; and of the second, Zones of Increased Density in Growing Bones and Underlying Mechanisms.

University of Dublin

Dr. F. M. R. Walshe, F.R.S., is delivering the Frederick Price lecture on Friday, April 24, at Trinity College. He is speaking on the Interpretation of Clinical and Experimental Observation in Neurology. On Tuesday, April 28, Prof. Alf Brodal, of the University of Oslo, will give the John Mallet Purser, lecture on the Pyramidal Tract in the Light of Recent Anatomical Research. Both lectures are at 4.30 P.M.

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the faculty on April 13 with Dr. Andrew Allison, the president, in the chair, the following were admitted fellows of faculty:

E. B. Hendry, Sheriar Jamshed Irani, J. H. R. Ramsay, Chellappa Ratnavel, R. S. Walker, qua physician; Muhammad Ismet Anwar, qua surgeon.

Almroth Wright Lectures

Dr. Leonard Colebrook, F.R.S., will give the first of this series of weekly lectures which is to be held at the Wright-Fleming Institute of Microbiology, St. Mary's Hospital Medical School, London, W.2, on Tuesdays at 5 P.M. from May 5 to June 16. Dr. Colebrook is to speak on Almroth Wright—Pioneer in Immunology. The other lecturers are: Mr. J. G. Davis, D.SC., Brigadier J. S. K. Boyd, F.R.S., Prof. C. L. Oakley, Prof. J. R. Squire, and Prof. Gerhard Domagk. Further particulars will be found in our advertisement columns.

International Congress of Blood Transfusion

The fifth International Congress of Blood Transfusion will take place in Paris from Sept. 13 to 19, 1954, immediately after the International Congress of Hæmatology, which will be held from Sept. 6 to 12. Further information can be had from Colonel (méd.) Julliard, 57, Boulevard d'Auteil. Boulogne sur Seine, France.

Irish Medical Schools and Graduates Association

At the annual dinner of this association at the Rembrandt Hotel, London, S.W.7, on May 7, Dr. W. R. F. Collis, the president, will present the Arnott medal to Mr. Terence Millin, and will invest Mr. Ian Fraser with the badge of presidency for the coming year. The hon. secretaries of the association may be addressed at 149, Harley Street, W.1.

Kingston and Malden Victoria Medical Foundation

The first report of this foundation, established in 1951 with the aim of setting up a new voluntary hospital, shows that in the *nineteen* months up to Dec. 31, 1952, receipts totalled £9747. Expenditure amounted to £2918, leaving a balance of £6828.

Stock-taking Time for Nursing

Opening the new preliminary nurse training-school at Orpington Hospital on April 16, Miss Patricia Hornsby-Smith, parliamentary secretary to the Ministry of Health, said that although the total nursing force had reached a record level of over 167,000, there were increasing claims on the country's woman-power. "It is, therefore, essential," she said, "that the time and skill of every nurse should be properly and efficiently used, and at this moment there is, as it were, a stock-taking in the nursing profession. "To make the best use of available nurses we must decide what were the proper tasks of the nurse, and the Minister had invited his Standing Nursing Advisory Committee to set up a small study group to report on the practical implications of this problem.

Areas in Scotland Needing More Doctors

A revised list of areas needing more family doctors has been prepared by the Scottish Medical Practices Committee, and is being issued to executive councils throughout Scotland. The Department of Health state that an initial practice allowance will be payable to a doctor setting up in single-handed practice in these areas.

Association of Occupational Therapists

This association is holding a conference at Church House, Westminster, London, S.W.1, from April 30 to May 2. Lord Webb-Johnson will open the conference, and other medical speakers will include Sir Russell Brain, P.R.C.P., Dr. Morris Markowe, Dr. J. G. Howells, Prof. J. Whillis, Mr. John Barron, Mr. J. P. Heron, and Prof. R. E. Tunbridge. Further particulars may be had from the secretary of the association, 251, Brompton Road, London, S.W.3.

Blood Donors

In 1952 gifts of blood to hospitals in England and Wales through the National Blood Transfusion Service totalled 647,009—over 50,000 more than in the previous year. It was the highest total since the record of 669,000 in 1944. 107,881 new donors were enrolled, and the donors' panel at the end of the year numbered 487,660; but the service still needs over 135,000 more donors, to do away with the need to call on anyone more than twice annually, to make good the loss of those reaching the retiring age of 65, and to provide a reasonable reserve of blood-plasma.

Association of British Pharmaceutical Industry

Speaking at the annual dinner held in London on April 15, Mr. Iain Macleod, the Minister of Health, said that the total bill for pharmaceutical services in the National Health Service was about £60 million a year, of which about £7 million was paid by patients. He was not much comforted when told that, looking at the cost of the service as a whole, this represented only about a penny in the shilling: by any reckoning £60 million was a vast sum—only a million or two less than what was needed to take 6*d.* off the income-tax. He well knew that the pharmaceutical industry made a very important contribution to exports and also that it was very important to continue the research that had brought such benefits. But he thought it fair to tell the industry that this Government, like the previous Government, was deeply concerned over the size of the drug bill—a subject that was (to use an official bromide) under earnest and constant and continuous review. He was, he added, deeply conscious of the industry's assistance to the Ministry, which had always had its willing and public-spirited coöperation.

Mr. Charles Saul, president of the association, said that the industry was more than anxious to help in effecting economies in the N.H.S. The cost of certain drugs was high, but so was the cost of research and of production; and the use of expensive drugs could be an economy if they shortened illness. The money value of the industry's exports had risen from £3·28 million before the war to £31·65 million last year, and every effort would be made to improve on that figure. But at no time had the industry been faced with greater difficulties than those of today—currency and quota difficulties, import restriction difficulties, and registration difficulties, to say nothing of increasingly severe competition from the U.S.A., Germany, the Continent, and even Japan and certain countries which benefited from incentives on exported goods. A new difficulty was the attempt in certain Continental countries to link the selling price in those countries *to the retail selling price in the country of origin*—a policy that would defeat its own object because the low-priced preparations would be driven off the market. While the Ministry of Health naturally pressed for the lowest possible price for all medicaments, the Board of Trade, wanting the greatest possible volume of exports, was not unwilling to see the manufacturer get a high price for his product. It was just not practicable, however, to charge a low price in this country and a much higher price abroad—one reason being that foreign importers could buy the product here through their agents. Exhorted to reconcile two irreconciliable policies—one to keep down prices in the home market, the other to increase export revenue or die—most manufacturers would undoubtedly prefer to export. If there were a single central body which at the highest level could look at any problem from the domestic and export standpoints simultaneously, the industry would give it full coöperation.

Mr. Richard Law, M.P., replied to the toast of The Guests.

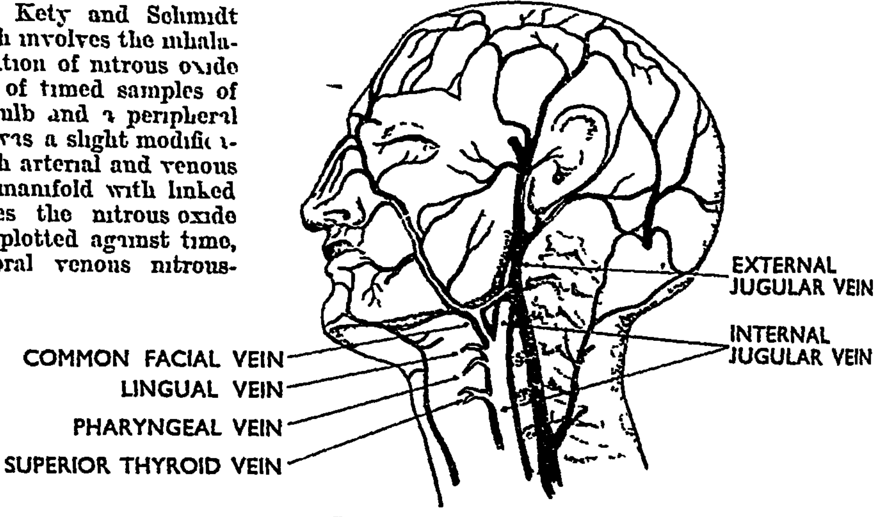

Fig 3—Venous anatomy

In the first 2 cases the estimations were made according to the original technique of Kety and Schmidt (1945, 1948) and Kety (1948), which involves the inhalation of a non-anæsthetic concentration of nitrous oxide for ten minutes and the removal of timed samples of blood from the superior jugular bulb and a peripheral artery during this period There was a slight modification in that one operator drew both arterial and venous specimens by means of a double manifold with linked pairs of syringes In these cases the nitrous oxide concentration in the samples was plotted against time, and the integrated arterial-cerebral venous nitrous-oxide difference $(\int_0^{10}(A-V)dt)$ was calculated from the curves by the trapezoid rule, relevant corrections having been made in the timing and for the dilution due to the dead-space volume of the catheter and tubing Otherwise the calculation was as described below

In the subsequent 4 cases the modification due to Scheinberg and Stead (1949) was adopted and continuous constant-rate withdrawal from artery and jugular bulb was maintained during the ten-minute period, the nitrous oxide content of each sample then represented the integral value for the whole period

It seemed to us that manual withdrawal at a constant rate was subject to an undesirable degree of human error and an electrical device was therefore constructed for the purpose Timing was by stopwatch and allowed for the evacuation of the dead-space volume, which was filled with heparinised saline solution, subsequent corrections were made for the corresponding dilution of the samples In other respects the technique resembled that of Scheinberg and Stead, a cerebral venous blank being taken immediately before each estimation, and final arterial and cerebral venous specimens at the end of the ten-minute period, nitrous oxide inhalation was continued until the latter were collected Arterial sampling was through an indwelling needle placed in either the left brachial or the left femoral artery The nitrous oxide mixture, which was supplied commercially (N_2O 15%, O_2 21%, N_2 64%), was conducted to either a face mask or a mouthpiece by way of a system incorporating an anæsthetic bag and inspiratory and expiratory valves Steps were taken to guard against possible leakages in this system

The blood samples were analysed for nitrous-oxide content in a Van Slyke Neill manometric apparatus according to the technique of Orcutt and Waters (1937), modified by Kety and Schmidt (1948) The analyses were all done by one of us (A R J), and eight pairs of duplicates submitted for statistical analysis showed a standard error of ±0 1 mm The mean cerebral blood-flow (C B F) was calculated from the formula

Mean C B F (ml of blood per 100 g of brain per minute)

$$= \frac{CV_{10} \times S \times 10}{\int_0^{10}(A-V)\,dt}$$

where CV_{10} is the nitrous oxide content in volumes % of the cerebral venous specimen taken at the end of the tenth minute S is the partition coefficient of nitrous oxide between brain and blood

$$\frac{\text{Solubility of N}_2\text{O per g of brain}}{\text{Solubility of N}_2\text{O per ml of blood}}$$

which has previously been found to approximate to unity (Kety et al 1948) and $\int_0^{10}(A-V)\,dt$ is the integral of the arterial cerebral venous nitrous oxide difference over the ten-minute period determined from the difference between the nitrous oxide contents of the two integrated specimens The theory and validity of the procedure have been extensively discussed elsewhere (Kety and Schmidt 1945 1948, Scheinberg and Stead 1949)

Arterial blood-pressure was measured by the auscultatory method in the right arm before, during, and after each estimation of blood-flow, and the mean arterial pressure for the period was calculated by adding a third of the average pulse pressure to the average diastolic pressure

The cerebral vascular resistance (C V R in C V R units) was taken as the quotient

$$\frac{\text{Mean arterial blood pressure in mm Hg}}{\text{Mean C B F in ml blood per 100 g brain per minute}}$$

A C V R unit may be considered as the mean pressure in mm Hg required to drive 1 ml of blood through 100 g of brain in one minute The theoretical standard error of the estimation of C B F in this way depends on the standard error (S E) of the manometric readings and on the magnitude of the difference in nitrous oxide saturation between the continuous samples of arterial and cerebral venous blood

Where the S E on the manometric apparatus is ± 0 1 mm the S E of the C B F method expressed as percentage of C B F is ± 3 5% for a difference of 4 mm in the manometric readings of samples $\int_0^{10} A\,dt$ and $\int_0^{10} V\,dt$ and decrease to a value of ± 2 3% for a difference of 6 mm Where the S E of manometric analysis is ± 0 2 mm these are correspondingly doubled The S E of C V R estimation is about ± 5%.

It was not considered justifiable to submit patients to successive C B F estimations to see how far observed differences confirmed these estimates, but duplicate estimations done in one patient were well within the predicted range Further, four other pairs of successive estimations performed under conditions which would not have been expected on a priori grounds to alter the C B F significantly all showed agreement within the range of the theoretical standard error It was thus thought unlikely that any other [illegible] variables were operating in the method as performed by us

With a single exception, no sedatives were given, and cardiac premedication was limited to quinidine gr 3 by mouth, which was administered at least two and a half hours before the first estimation of blood flow The exception was patient no 2, who received quinidine gr 6 and 'Sodium amytal' gr 3 by mouth three hours beforehand

The catheter was kept clear by a slow drip of heparinised physiological saline solution during catheterisation of the heart and between the first and second estimations of C B F Procaine was not used except for the intravenous injection of not more than 1 ml of [illegible] solution of the hydrochloride when the catheter was first introduced into the left antecubital vein Th

BEHAVIOUR IN CHILDHOOD*

NORMAN B. CAPON
M.D. Lpool, F.R.C.P.
PROFESSOR OF CHILD HEALTH IN THE UNIVERSITY OF LIVERPOOL

"... 'Tis Nature's plan
The child should grow into the man."—LONGFELLOW.

WE use the word "behaviour" in many different senses, and sometimes apply it even to inanimate objects. I should explain therefore that what I have in mind here is much more than the display of any single characteristic, such as deportment, sociability, or even personality; I am thinking of the sum total of an individual's activities, whether they spring from deliberate taking of thought, or whether they are due to habit or to subconscious reflexes.

Naturally the components of human behaviour are extremely complex; and the pattern is constantly changing. Just as a flower bears little resemblance to the seed from which it has grown, so in the transformation of behaviour from childhood to adult life the picture is likely to alter out of all recognition; or, to vary the metaphor, the central core of behaviour displayed during early life is sure to be concealed under the new accumulations of experience added year by year. Nevertheless the process is one of evolution, each successive phase bearing some sort of relation to what has gone before. Behaviour during childhood is in some measure the mould which gives shape and form to subsequent development.

Individuals and Groups

There are at least three ways of considering behaviour in childhood. The first is to take individual children and to observe their actions and how they conduct themselves in various circumstances. This is the way that interests most parents; it is personal, intimate, and factual. A second way is to select certain groups of children, and note whether the behaviour of the individuals composing each group has features that are common to all, or perhaps to a majority. Examples of such groups might be "only" children; or children born into the so-called problem families; or the children of artistic parents, like musicians or poets; and I might also add other groups—if it were not to tread on dangerous ground—such as the children of pædiatricians or of psychologists.

The third way is to consider the behaviour of much larger groups of children, and to face up to questions that have to be answered on the basis of general impressions rather than detailed observations. Can we, for instance, claim that the children of today have better manners than those of a hundred years ago? Is childhood delinquency on the increase or not? Does the use of political propaganda in schools in certain countries affect the character and conduct of the pupils when they become men and women? These are problems that greatly concern statesmen, politicians, sociologists, the members of debating societies, and indeed each one of us; but I need not remind you that generalisations are easily made but seldom convincing, and one must always be cautious both in making and accepting them. And whether or not we decide to tackle such interesting but elusive problems, we must first give some thought to the "individual" mode of approach, and ask ourselves about the factors that probably play a part in determining the behaviour of children.

Tendencies

Undoubtedly there are inherited tendencies, but these are curiously bizarre in their transmission; and when a child displays a parent's characteristics there is always the possibility that mimicry rather than heredity has been responsible. (One fact stands out in my experience—that any unfavourable trait shown by a child is commonly ascribed by the mother to direct transmission from the father's side of the family.) Then there are those strange and amazingly vigorous urges that we call instincts: these play a big part, especially in regard to feeding and to self-preservation, and though they become modified by experience and memory they are potent directives of behaviour during the whole of childhood. And there are many other instincts, less fundamental though still noteworthy: of these I will mention only the urge to dominate others and to have possessions: the herd instinct, linked with social customs and with local loyalties, whether to school or to crime-gang: and the instinct to explore and gain experience, which later may become the most significant weapon used by the scientist, the theologian, or the expert burglar. And behind all these instincts there works the inexhaustible energy of childhood, giving momentum and, as we adults often think, inexplicable direction to their activity simply because the child's reasoning capacity is underdeveloped. As one little boy said to me when I mildly rebuked him for his restless and rather foolish behaviour, "But I never know what I'm going to do until I've done it."

Sensations

The power of discrimination is also immature in childhood, but it may be seen even in the instinctive behaviour of animals still in their infancy; and a human baby will not suck and swallow more than a mouthful or two of a bitter solution offered instead of milk. It would be idle to pretend that this choice in respect of diet in infancy possesses the full conscious significance of an adult's preference for, say, a dry sherry, but it is certainly a more elaborate and selective response than the contraction of a muscle in a nerve-muscle preparation. And at an early age—certainly by the third month—a baby indicates, by smiling or grimacing, that his actions bring him contentment or vexation, that is to say a range of feelings less sharp-edged than vivid pleasure or pain. These sensations, which later become increasingly complex, like a spectrum of colours derived from a single beam of white light, eventually play a part in fostering those conscious choices which the adult describes as preferences, tendencies, leanings, and so forth, and undoubtedly constitute an important factor in determining behaviour. And even in early life, their expression by facial and bodily movements is a channel by which the child makes his contribution to the to-and-fro tossing of messages between himself and the people that surround him.

The younger the baby, the smaller is his space-world—that is, the surrounding area available to him for gaining experience. Things must touch his skin, and objects must be placed immediately in front of his eyes, before he becomes aware of their presence; and as yet his brain can make only a crude interpretation of the impressions received by his sense-organs. But soon, with the gradual opening up of nervous pathways between his eyes, ears, and brain, he learns to follow the movement of a bright object or attractive sound, and then he puts out his hand to grasp it. But he shows little diagnostic acumen—for instance, he would try to take hold of a red-hot poker. Nevertheless, these active responses of the young baby to things happening within his very circumscribed world are the beginnings of his adventure out into the larger world—a development that will proceed much more quickly when he learns to move about the room, at first crawling and later walking. When children are slower than normal in their development the fault may lie in their sight, hearing, brain, or

engineering, King's College Newcastle upon Tyne, for constructing the syringe withdrawal device, to Mr H Campbell for his invaluable aid with the statistical analysis, to Dr Whately Davison and Dr C K Warrick for radiological facilities, to Mr C J Duncan and his staff of the department of photography, King's College, Newcastle upon Tyne, for the reproduction of the radiographs and for the diagram of the venous drainage of the head, to Dr N A Wynne for help and criticism, to Mr L P Lassman, of the department of neurosurgery, Newcastle General Hospital, for the observation referred to in the text, and to Mr T Copeland for his willing help at all stages of the investigation

Addendum

Since this paper was written, a group of workers in the United States have reported on the effects of intravenous tolazoline on the cerebral circulation (Scheinberg et al 1953) They did not observe any significant change in cerebral vascular resistance in the patients studied, most of whom belonged to the age-group when cerebral vascular disease is usually present though not clinically evident It seems likely that tolazoline is not effective in such patients

PROGNOSIS AND TREATMENT IN ACUTE PERFORATED PEPTIC ULCER

A REVIEW OF 206 CASES

JOHN GILMOUR
M.B, M S Durh, F R C S
SURGEON, ROYAL VICTORIA INFIRMARY, NEWCASTLE UPON TYNE

THE annual number of admissions for peptic ulceration and its complications at the Royal Victoria Infirmary, Newcastle, averages about 1400 Of this total acute perforations account for about 15% I review here the 206 cases of acute perforation in peptic ulcers admitted under my care in 1946–50 and examine the possibility of making a prognosis which would be a guide in their treatment Although we know that some patients appear to be "cured" of their ulcers for long periods after surgical suture of their perforations we do not yet know how to distinguish these at operation from those who suffer recurrent ulceration

The 206 patients were operated on by different members of my clinic They were all treated by laparotomy simple suture of the perforation and toilet of the peritoneum combined with the use of sulphonamides or other antibiotics when necessary and postoperative gastric suction *Modern methods of anæsthesia* facilitated operation and diminished chest complications Several points of general interest call for brief comment

ULCER SITES AND DISTRIBUTION BY SEX

TABLE I—AGE DISTRIBUTION IN 206 CASES OF PERFORATED PEPTIC ULCER

Age (yr)	Males	Females	Total
10–19	1	—	1
20–29	43	1	44
30–39	43	1	44
40–49	44	4	48
50–59	35	—	35
60–69	26	1	27
70–79	4	—	4
80 or more	3	—	3
Total	199	7	206

This series of perforations comprised 160 duodenal ulcers (77 7%), 43 gastric ulcers (20 8%), and 3 stomal ulcers (1 5%) 199 (96 6%) were in males and 7 (3 4%) in females, 4 being duodenal and 3 gastric Of the 43 gastric perforations 24 were on the lesser curve, 11 on the pyloric canal and 8 on the body of the stomach The high percentage of duodenal cases accords with general experience, and the preponderance of males over females is striking

Though men suffer more than women from peptic ulceration, acute perforations seem to occur much more often in men In 1950 if perforations are excluded, 1210 patients with peptic ulcer were admitted to the R V I Of these, 1030 were males and 180 were females—a ratio of 5 7 males to 1 female The same year there were 187 acute perforations, 179 being in males and 8 in females—a ratio of about 22 males to 1 female In the present series the ratio is 28 males to 1 female Men with peptic ulcer thus appear to be between four and five times as liable to perforation as are women with ulcers

No adequate explanation has yet been given of the relative immunity of the female sex to peptic ulceration DeBakey (1940) recalls the suggestion that it may be due to a protective mechanism which is *hormonal* and operates during the years of sexual maturity, particularly during pregnancy In the search for the cause of peptic ulceration or its prevention this aspect of the problem should not be overlooked

AGE-DISTRIBUTION

Table I shows the age distribution in the present series. A prominent feature of this table is the relatively even distribution of the cases between the ages of 20 and 59 The oldest male was 85, and the oldest female 67 The youngest male was 10, and the youngest female 21 The average age of the males was 44, and of the females 42, 43% of the ulcers perforated before the age of 40, and 57% after that age The statistician who has reviewed these figures states that an interesting comparison can be made between the age distribution of males with perforations and the age distribution of all males in the Northern Region at the 1951 census (table II)

Although it is difficult to argue from hospital admissions to the incidence in the whole population, the R V I has always received most of the surgical emergencies from Newcastle and the county of Northumberland, and acute perforations have consistently totalled about 200 annually for many years The figures do not suggest that there is any particular period of adult life when males are more susceptible to perforation The fall in the incidence of perforation in later years corresponds to the smaller adult male population in those years It thus appears true that peptic ulceration occurs throughout the years

TABLE II—COMPARISON OF AGE DISTRIBUTION OF PERFORATIONS IN MALES WITH AGE DISTRIBUTION OF ADULT MALES IN NORTHERN REGION AT 1951 CENSUS

Age (yr)	Males in Northern Region 1951	Percentage of adult males	Number of perforations in males	Percentage of perf in males
20–39	451 000	43	86	43
40–59	390 000	38	79	40
60 or more	200 000	19	33	17

conviction by intellectual means; while in defiance of such reasoning, as he wrote, the small girl turns with indifference from the expensive doll, to cherish her beloved golliwog which lives and moves and has its being at her word, which comforts her in sorrow and soothes her at last to sleep.

Home

In speaking of the relationship of children with adults, I have so far limited myself to some observations upon the characteristics of the child. What can be said of the adults and their contribution? This is where a knowledge of abnormal tendencies in childhood behaviour comes in to support the view—now widely held in this country, but not always put into practice—that the stability of home life, and the exercise of reasonable, fair, and consistent discipline provide what most children need for the full development and maturation of their potentialities.

To speak of home life is to run the risk of giving way to sentiment, and after two world wars our mood is to take a tight grip of ourselves and to do what we can to keep our emotions in check; so please bear with me if I quote Ruskin's words "This is the true nature of home—it is the place of peace; the shelter not only from all injury but from all terror, doubt and division." This is a sensible statement, and the general idea it contains may be backed up, in lighter vein, by reminding you of Winston Churchill's shaft of ridicule when the Government of the day was toying with the idea of substituting the words "accommodation unit" for the older term "house" or "home." He pointed out that the modern version of "Home, sweet home," would now be "Accommodation Unit, sweet Accommodation Unit, There's no place like my Accommodation Unit"; and by this sally of humour he made a telling point.

When a child's home circumstances are satisfactory he enjoys the care and affection of his parents, the friendship of brothers and sisters, decent living conditions, and many other blessings that are perhaps too obvious to mention. But I doubt if we fully appreciate their influence upon his behaviour unless we make a contrast and review the lives of children living under less satisfactory conditions—not only the so-called problem children and the delinquents, but also those relatively less distressing cases that some of us meet daily in professional practice.

Two years ago I analysed, for another purpose, a series of 450 children referred to me with complaints which seemed to me to be due to their upbringing rather than to any physical disease or to subnormal intelligence. In such a series the complaints are found to be varied, and therefore difficult to classify satisfactorily. I divided the children tentatively into four groups, the first including habit spasms, some speech disorders, and breath-holding attacks; the second, abnormal forgetfulness and incapacity for mental concentration; the third, cases characterised by anxiety neuroses, phobias, including night-terrors, refusal to eat, sleep, and play, abnormal outbursts of temper, and so forth; and the fourth group, children with antisocial behaviour, such as pilfering, truancy, and cruelty to other children and animals.

By studying the histories of these children I was able to form an impression of the home conditions under which they had been living. One could not expect, of course, to find any common pattern—human life is far too varied for that; but I was convinced that the lives of most of them had lacked one or both of those two cardinal advantages which I have previously mentioned—namely, security at home, and reasonable discipline. As examples of insecurity at home I would instance death of one or both parents; divorce; discord or loss of agreement and mutual respect between parents; and the unwanted child. Such children are liable to become the victims of what I can only call emotional ill health; and the efforts made by other relatives, such as grandparents, to give the affection that has been denied to them, are not always successful, chiefly because they are likely to be tinged with "over-protection," or excessive care to guard the child from further accident or distress. Under these circumstances the spirit of adventure is opposed, the healthy urges of childhood are too much restricted, and the child's reaction may be a disorder of behaviour. Similarly, when there is a lack of discipline the child is liable to become unattractive, wilful, or perhaps highly nervous, strained, and fretful. For the essential basis of discipline is that adults should make decisions for the child in respect of those matters which his understanding cannot fully comprehend, and should require compliance with their orders. And the most successful parents teach by their personal example even more than by their commands; they make the most of those childhood characteristics of mimicry and hero-worship to which I have already referred. Furthermore, they do what they can to allow the child some latitude for trial and error in order that imposed discipline may become the ground plan upon which the highest form of discipline—namely, self-discipline or self-control—is built up.

The Less Fortunate

These thoughts based upon experience with children at our own social level lead naturally to the question of behaviour as shown by the children of the masses, especially in large industrial areas. If you turn your minds for a moment to the early years of the industrial age when such men as the seventh Earl of Shaftesbury, William Farr, Sir John Simon, Sir Edwin Chadwick, and Charles Dickens were among the pioneers of reform, you will be shocked to find that the public conscience was so deaf and blind to the disreputable conditions under which many children lived, and all too frequently died. As Simon wrote in one of his masterly reports (1857):

> "Those places where infants are most apt to die are necessarily the places where survivors are most apt to be sickly; and where, if they struggle through a scrofulous childhood to realise an abortive puberty, they beget a still sicklier brood than themselves, even less capable of labour and even less susceptible of education. It cannot be too distinctly recognised that a high local mortality of children must almost necessarily denote a high local prevalence of those causes which determine a degeneration of race."

The five giant evils that in more recent years formed the main topic of the Beveridge report—namely, want, Disease, Ignorance, Squalor, and Idleness (or as we should today say, Unemployment) were rampant on all sides. Children of tender years were putting in long hours of work in mills, factories, and other places of employment, and even in 1869 the Registrar-General's report recorded the deaths of 145 children under the age of fifteen who were killed in coalmines, and 2 of these victims were under the age of ten years. Samuel Hutton has recorded that at seven years of age he was set to work in a silk mill, where he toiled each day from 5 A.M. until 7 P.M. for the weekly sum of one shilling. "This," he wrote, "paid for my board and lodging, and rendered me independent of my father, except for the clothes I wore."

In those times families were large, and the parents in the social group under consideration were uneducated and expected nothing better than a life of toil and drudgery, and a never-ending struggle against penury. Naturally it was upon the children that these dreadful conditions operated most harmfully; yet it can be said that in these families, hedged in by so many threatening forces, the bonds of affection were fostered and it would be wrong to conclude that the children lived stunted lives emotionally, no matter how much they suffered physically and through the frightening ordeal of their episodes of medical or surgical treatment in hospital for pain, for bleeding, or for previous perforation

Modes of Perforation

The records show that the perforation occurs in one of two ways

(1) As the culminating crisis in an attack of peptic ulceration, or

(2) As a sudden event with no preliminary symptoms of dyspepsia

In the first instance a painful dyspepsia leads up to the moment of perforation, whereas in the second case this feature is absent In the former the perforation may be visualised as the result of active ulceration In the latter the catastrophe strikes the patient when he is apparently in normal health, and the underlying pathological process is painless Whatever the true explanation of these two modes of perforation, they occurred in cases of both acute and chronic ulceration and in considerable numbers

Pathological Appearances of Perforation

There is usually no difficulty in recognising the type of perforation present at operation

In *acute ulcer perforations* the stomach or duodenal wall is pink or red and mobile, and the perforation is small After preliminary symptoms the wall surrounding the perforation has become œdematous and soft, making sutures tend to cut out, the colour is whitish-pink, the perforation is small, and the bowel is still mobile After a longer period of ulceration before perforation there is more induration of the wall, the peritoneal coat is thicker and whiter, the perforation is less easy to infold with sutures, and the parts remain mobile

In *chronic ulcer perforation* the hole may still be small but it tends to be larger than in the acute ulcer The condition of the wall reflects previous pathological changes It is usually more fibrotic and stiff and may show some scarring, mottling, and deformity There may be thickening of the peritoneal folds, particularly of the lesser omentum, leading to deep fixation which interferes with mobility There may be adhesions between the ulcer area and neighbouring viscera, or penetration into the liver or pancreas Sometimes stenosis complicates the picture, or a posterior ulcer increases the deep fixation

Thus, by correlating the preoperative clinical history with the pathological changes found at operation, the type of ulcer associated with each perforation was diagnosed, and the results are set out in table IV The most noteworthy feature which emerges from this study is the relatively high proportion of acute ulcer perforations (64%) to chronic-ulcer perforations (36%) in this series This conflicts with the commonly accepted view that most perforations occur in chronic ulcers, but it is confirmed by the investigation of the late results, which, though very uniform in each type of ulcer, are different in character

Table IV also shows the distribution of the two modes of perforation Symptomatic ulceration ending in perforation occurred in 103 cases (57%) and sudden acute perforation in 78 cases (43%) Acute perforation was the first and only symptom in 16 cases (9%)

TABLE IV—CLINICAL TYPES OF PERFORATING PEPTIC ULCERS

Type of ulcer	Previous history	Mode of perforation		Total	
		During attack of dyspepsia	With no symptoms of dyspepsia		
Acute	None	35	16	51 (28%)	116 (64%)
	Vague	31	34	65 (36%)	
Chronic	Recurrent	37	28	65 (36%)	
Total		103 (57%)	78 (43%)	181	

TABLE V—RELATION OF CLINICAL TYPES TO LATE RESULTS

Type of ulcer	Late result		Relapses		Total
	Satisfactory	Moderate	Medical	Surgical	
Acute	62	28	15	11	116
Chronic	—	—	24	41	65
Total	62	28	39	52	181

Prognosis in Perforations of Acute and Chronic Ulcers

In seeking to establish the prognosis the after history of each case was assessed, and table V gives the results This shows the clear contrast between the after histories of acute and chronic ulcers

Of the 116 acute ulcer cases 62 (54%) were satisfactory, 28 (24%) were moderately good, and 26 (22%) were poor results Thus, the ultimate prognosis of perforating acute ulcer is good in more than 75% of these cases, less than 25% tend to relapse, and less than 10% required further surgery It should also be remembered that there were no deaths in this group

In contrast with this the ultimate prognosis of perforating chronic ulcers is poor in all cases Of the 65 chronic-ulcer cases all relapsed, 24 required further medical treatment, and 41 had already undergone further operation for perforation, for hæmorrhage, for stenosis, or for painful crises causing loss of work As a group they account for 70% of all the relapses in the series Further, it should be recalled that the immediate mortality rate of this group was 15%

Such differences in the immediate and ultimate prognosis of perforations in acute and in chronic peptic ulcers clearly indicate the need for individual consideration

METHODS OF TREATMENT

Laparotomy and simple suture are a life saving procedure, safe and adequate for the acute ulcer which perforates, but less so for the chronic ulcer The results of published series of perforations have shown a considerable drop in the mortality-rate comparable with that of the present series, but this mortality is almost wholly due to perforations in chronic ulcers, which form the kernel of our problem and are responsible for more than 70% of all relapses What alternative method is there which will yield better results in perforated chronic ulcers ?

The ideal treatment for perforations would, of course, be preventive in known cases of chronic ulcer Medical treatment, however, is powerless to prevent it, as witness those ulcers which perforate while undergoing medical treatment even in hospital Surgical intervention before the age at which the mortality from perforation begins to mount—i e, 40–45—therefore seems to offer the best hope Failing this prophylactic attack, acute perforations will continue and alternative methods of treatment require to be considered

The conservative method of treatment was first advocated in this country by Hermon Taylor (1946) who used continuous gastric aspiration, intravenous fluid replacement therapy, and antibiotics to tide the patient over the crisis of acute perforation Surgical measures are held in reserve to deal with the residual collections of fluid in the abdomen, with cases in which escaped air accumulates in the peritoneal cavity, and with cases which do not respond to aspiration and which show signs of peritoneal infection This method requires constant vigilance from a team of trained and enthusiastic surgeons and nurses, along with routine radiography It depends on the natural defensive reactions of the peritoneum to close the perforation Various reports indicate that this method yields a mortality rate of 8–10% More important is the observation that it that shuns meanness and is unselfish, gay, and reverent; a nature that is sociable and attractive. It is usual to find that these qualities evolve gradually; like good wine, they take years to mature. But—and this is my final note—the more closely human life is viewed, the more unexpected seem its twists and turns.

I cannot claim to have done more than bring to your notice some of the factors affecting children's behaviour, which in turn bears a relation to the behaviour and character of adults. The Welfare State, with all its advantages, has still not found the key that will unlock the hearts of the people, wherein are stored fine qualities that need an airing. Let me quote to you a sentence from Lord Radcliffe's Reith lectures, 1951.

> "The British have formed the habit of praising their institutions, which are sometimes inept, and of ignoring the character of their race, which is often superb. In the end they will be in danger of losing their character and being left with their institutions; a result disastrous indeed."

Is there not a good case for believing that of all the resources given to men to guide their future none offers better promise than the upbringing they give to their children? For in it lies one of those potentialities that "makes mighty things from small beginnings grow."

AMINE OXIDASE, PRESSOR AMINES, AND CHOLINESTERASE IN BRAIN TUMOURS

This investigation was undertaken to ascertain whether, besides serving as a supporting and nutritional tissue, neuroglia participates in the formation and breakdown of substances such as acetylcholine, adrenaline, and noradrenaline which play a part in the transmission of nervous impulses. All samples of the central nervous system are necessarily a mixture of nervous tissue and neuroglia; but by examining samples of brain tumours, particularly glioma tissue, we hoped to obtain some correlation between enzyme activity and the histological classification of the tumours—i.e., the preponderance of certain cell types. Some of the results have already been briefly reported (Bülbring 1953).

The presence of amine oxidase in the central nervous system was first shown by Pugh and Quastel in 1937, and Nachmansohn (1939) first studied in detail the distribution of cholinesterase in the brain. Birkhäuser (1940) published quantitative data on the contents of both enzymes in certain areas of the human brain. The findings of Ord and Thompson (1952) on cholinesterases and of Thompson and Tickner (1952) on amine oxidase in human brain were obtained by the same technique as we have used and are therefore more suitable for comparison with our results obtained in brain tumours. Noradrenaline and adrenaline have been found by Vogt (1952a and b) in certain parts of cats' and dogs' brains.

MATERIAL AND METHODS

Samples from twelve intracranial tumours removed at operation were studied, adjacent portions being used for histological, biochemical, and pharmacological investigation. Seven gliomas of the astrocyte series (one in a child), one ependymoma, one acoustic-nerve tumour, and three meningiomas were studied. The meningiomas, which do not originate from brain tissue, and the acoustic-nerve tumour served to some degree as controls. The gliomas showed a mixture of cell types and varied in the amount of anaplasia from tumour to tumour and from part to part of the same tumour. In table I the less anaplastic ones are designated astrocytomas and the more anaplastic ones glioblastomas. The presence or absence of mitoses is also indicated to give some guide to the degree of variation from normal adult tissue and the rapidity of growth. The histological sections of the meningiomas and the acoustic-nerve tumour showed no nerve-cells. Although in gliomas most of the cells are of glial origin, they are usually diffusely infiltrating tumours, and it is common to find nerve-cells even quite deep inside the tumour. In most of our cases there were at least some nerve-cells visible and in some cases fairly well preserved nervous tissue. Furthermore, in the centre of the tumour there was often much necrosis.

Enzyme activity was estimated manometrically by Warburg's technique. Adrenaline and noradrenaline were estimated by biological assay.

RESULTS

The amine-oxidase activity and content of pressor amines in the twelve tumours are shown in table I. Cholinesterase activity, using various substrates, is shown in table II.

With the exception of tumour no. 1, from a child aged 3 years, all the tumours were from adults. It was in the

TABLE I—ANALYSIS OF TUMOURS

Tumour no.	Age of patient (yr.)	Diagnosis	Mitoses	Presence of nervous tissue	Amine oxidase (µl. oxygen per g. per hr.)	Noradrenaline (µg. per g.)	Adrenaline (µg. per g.)

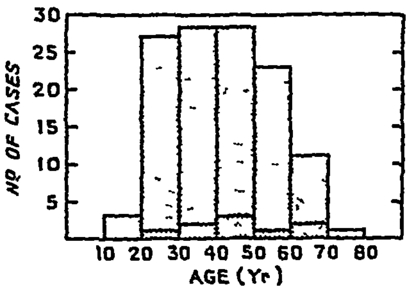
to control thyroid overactivity, and any toxic effect on bone-marrow and other extrathyroid tissues may be correspondingly reduced

Material and Methods

The 120 patients, of ages ranging from 16 to 72, comprised 92 with primary thyrotoxicosis (9 of them post operative recurrences) and 28 with toxic nodular goitre, the ratio of females to males being 12 5 1 (see figure).

DIAGNOSIS

In all the cases the diagnosis was established on the basis of clinical judgment, basal metabolic rate (B.M.R.), and radioactive iodine tracer studies uptake curve, thyroid plasma clearance-rate (Pochin 1950), urine excretion, and additional topographical survey in nodular glands Electrocardiograms were made in all the cases Serum-cholesterol and serum-creatine levels were also determined



Age and sex distribution in 120 cases of thyrotoxicosis stippled, female hatched, male

The size of the goitre was estimated clinically by palpation and the maximum neck circumference measured at intervals during treatment All glands removed at operation were weighed, thus providing a guide for subsequent clinical estimations The size of diffuse enlargements could be gauged fairly accurately, but nodular goitres were often underestimated owing to retrotracheal or subclavicular extensions inaccessible to palpation

Table I shows the distribution of different forms of thyrotoxicosis in relation to goitre size Goitres were classed as small when the estimated weight, or the weight of the gland removed, was up to 40 g Medium sized goitres had estimated or actual weights of 40–60 g Large goitres all weighed more than 70 g The cases were tabulated in this way, throughout the present study, to see whether a correlation could be found between the size and variety of goitre, the amount of drug required, and the rapidity of response to anti thyroid medication

TABLE I—TYPES OF THYROTOXICOSIS IN 120 PATIENTS

Size of goitre	Treatment		Primary thyrotoxicosis		Post-operative recurrent thyrotoxicosis		Toxic nodular goitre		Average initial dosage of neomercazole (mg daily)
	Curative	Preoperative	Curative	Preoperative	Curative	Preoperative	Curative	Preoperative	
Small	41	9	28	6	5	1	8	2	22 7
Medium	38	12	31	5	2	1	5	6	25 6
Large	11	9	10	3			1	6	29 5
Total	90	30	69	14	7	2	14	14	

NEOMERCAZOLE

At the beginning of this clinical trial neomercazole was given in small doses of 10–20 mg daily in accordance with the first published reports on the dosage of methimazole (Reveno and Rosenbaum 1950) Some of the slow responses to neomercazole in the patients treated early in this series are undoubtedly due to insufficient medication It is now considered that 15–20 mg daily is an adequate initial dose for mild cases with small goitres, 30 mg for cases of average severity, and 40–45 mg for severe cases with large goitres, or in patients with small goitres who respond slowly to 30 mg

Neomercazole is tasteless (mercazole is bitter) and is administered in tablets of 5 mg or 2 mg thrice daily

Clinical response was gauged by return of B.M.R. to normal, increase in body-weight, return of pulse rate to normal, loss of restlessness and tremor, and gain in general well-being of the patient The serum cholesterol level proved useful in assessing response a rise of 40% over the initial level confirmed other signs of over-treatment and occasionally helped to give warning of hypothyroidism before symptoms appeared A white cell count was always made before giving neomercazole Initial pretreatment counts below 4000 per c mm were sometimes found but were not a contra indication since they remained at the same level during prolonged administration of neomercazole White cell counts were not repeated as routine, since they provide no safeguard against agranulocytosis (Young 1949)

The B.M.R.† was estimated weekly in the preoperative group and in patients admitted to hospital for the initial period of medical treatment Most of the patients on curative treatment with neomercazole were treated entirely as outpatients and only spent one or two nights in hospital to undergo B.M.R. and I^{131} tests Most of them continued their usual occupations throughout the treatment Patients were seen fortnightly until their B.M.R. returned to normal, and subsequently every four weeks, with a B.M.R. test at each visit After six months the test was only done every two or three months

The preoperative group were given neomercazole for three or four weeks, with added Lugol's solution of iodine for five days before operation This group comprised patients with toxic nodular goitres, patients sent from distant towns where follow-up was impossible, and patients who did not respond rapidly enough and wanted an operation

As soon as the clinical condition and B.M.R. returned to normal, the dose of neomercazole was cut down gradually The rate of decrease of B.M.R. and the general improvement indicated how rapidly and to what maintenance level neomercazole could be reduced It was aimed to keep the B.M.R. between 0 and −5%, a few goitrogenic reactions occurred when it was allowed to drop below −10% After four to twelve weeks of the initial dosage neomercazole could be cut down in early remission to two-thirds or a half of the initial dosage, and after six months' treatment 5–10 mg a day sufficed for maintenance in average cases Mild thyrotoxics were maintained on 2 mg a day within three months Patients who responded slowly to neomercazole usually required higher maintenance doses, even after nine months' treatment Treatment was stopped when the patient was able to remain euthyroid on 2–5 mg of neomercazole daily for about six months To date, about twelve months' treatment has been found necessary Decrease in the size of the gland was also a good prognostic sign

Thyroid was administered together with neomercazole in 5 cases showing goitrogenic reactions due to over-treatment and in 2 patients with malignant exophthalmos

3 patients became pregnant while under treatment with neomercazole It is hoped to continue their treatment to term with the least amount of neomercazole necessary to keep the B.M.R. on the high side of normal (Astwood 1951)

WE present here the results of estimations of cerebral blood-flow by the nitrous-oxide method in 6 patients with mitral stenosis before and after intravenous injections of the vasodilator tolazoline hydrochloride ('Priscol'; 2-benzyl-4 : 5-imidazoline hydrochloride). This study arose from the desire to ascertain if there were a rational basis for the use of tolazoline in the emergency treatment of cerebral embolism.

So far as we are aware, no reports have been published on the effect of this drug on the cerebral blood-flow and vascular resistance in man.* Certain facts, however, suggest that it may influence cerebral hæmodynamics:

(1) Besides the cutaneous warmth in the extremities and face and the consciousness of increased cardiac action which follow intravenous injection of tolazoline, there develops also a sensation of fullness in the head which may become very intense at the height of the subjective effects (Ahlquist et al. 1947).

(2) Measurements of the retinal vessels have shown increase in calibre of the arterioles after the administration of tolazoline (Cholst et al. 1952). Engel (1952), using the skull-window technique, has demonstrated prompt dilatation of pial arteries and arterioles in the cat after an intravenous injection of tolazoline, an effect which he also observed in the presence of postconcussional vasospasm. A similar response of the pial vessels of man was recently observed during an intracranial operation (Lassman 1952).

(3) In patients with cerebral ischæmia improvement has been reported after treatment with tolazoline by mouth (Roch and Roch-Besser 1947).

(4) Smith and Turton (1951) have described the case of a patient with peripheral arteriopathy who was admitted to hospital suffering from depression and mental disturbance together with motor aphasia; his disability underwent a temporary but remarkable improvement in response to intravenous tolazoline, which was repeated on several occasions, control substances (physiological saline solution, vitamin B_1, and nicotinic acid) proving completely ineffective. More gradual improvement was later produced by oral administration, although ultimately tolerance to tolazoline developed. On the basis of this report and of the experimental work of Engel, the *British Medical Journal* (1952) has suggested that it might be worth while to make an extended trial of tolazoline in suitable patients with cerebral arteriosclerosis.

In view of these facts it seemed important to determine whether the brain participates in the increase in the total peripheral blood-flow produced by tolazoline.

Methods

Six patients, with mitral stenosis, undergoing routine cardiac catheterisation before valvotomy, were studied. The cerebral blood-flow was estimated in the supine position after measurement of the right-heart pressures in all the patients except case 3, in whom it was estimated immediately before.

The cerebral venous blood was sampled through a cardiac catheter, the tip of which had been placed in the left superior jugular bulb under fluoroscopic control.

The internal jugular vein joins the subclavian behind the inner end of the clavicle, and the catheter, which in each instance had been passed up the left arm, was rotated in the subclavian vein until its curved end pointed upwards, and there was usually not much difficulty in securing its entry into the left inferior jugular bulb. Rotating the patient's head to the right, depression of the patient's left shoulder, and deep expiration by the patient assisted this entry.

At the upper end of the inferior jugular bulb, about 1 in. above its junction with the subclavian vein, lie two valves. Sometimes the catheter passed through them swiftly and without any difficulty, but in other instances sharp obstruction was met, and then deep inspiration, compression of the opposite internal jugular vein, hyperextension of the head, and, on one occasion at least, rotation of the patient's head to the left, combined with withdrawal and readvancement of the catheter, usually overcame it.

The catheter was then advanced upwards to the base of the skull and, when its position there had been confirmed by fluoroscopy and radiographed, it was kept steady by tying it in the antecubital vein. Fig. 1 shows a catheter in position.

Rarely a catheter would stick short of the base of the skull, usually because its tip had caught in the junction of a tributary vein, but in most instances rotation enabled it to advance to the full distance. The cerebral blood-flow was not estimated unless this full advancement had been attained. The highest tributary bringing extracranial blood to the internal jugular vein is the common facial vein. Fig. 2 shows the catheter in this vein. Fig. 3 shows the venous anatomy of the region.

Catheters U.S. nos. 6, 7, and 8 were used at different times, and occasionally one size would pass where another would not.

Attempts to catheterise the left internal jugular vein succeeded in 15 of 22 patients (68%). Of the 7 failures, in 5 the catheter was held up at the valves, and in the 2 others it was arrested much higher; in 1 of these cases "stickiness" of the catheter in the veins was responsible, probably because of the time spent previously in catheterising the heart. Of the last 6 cases attempted, success was attained in 5. No complications were met with; 1 patient experienced pain in the ophthalmic division of the left trigeminal nerve; but this was promptly relieved by withdrawing the catheter a centimetre or so.

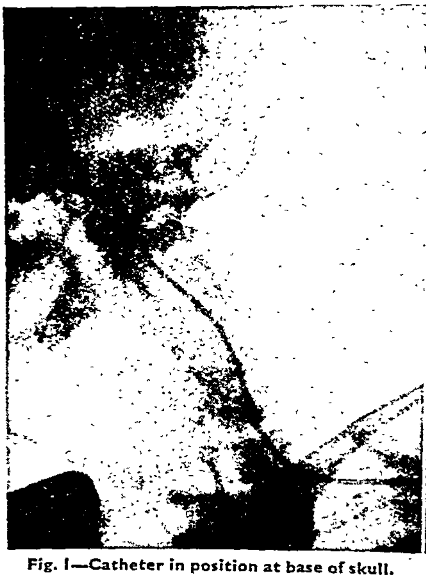

Fig. 1—Catheter in position at base of skull.

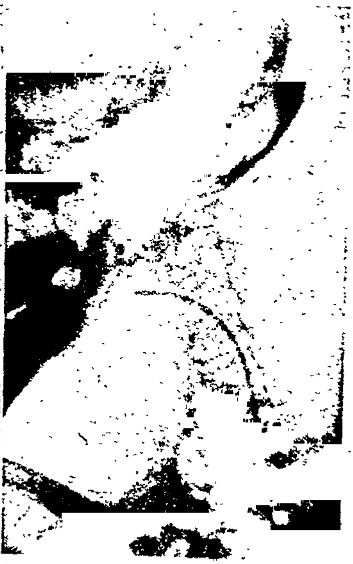

Fig. 2—Catheter in common facial vein.

---

* Such a report has appeared since this paper was written (see Addendum).

TABLE III—ANALYSIS OF 90 CASES TREATED CURATIVELY

Response to neomercazole	Size of goitre	No of patients	Average age and age range (yr)	Average initial B.M R	No of patients with primary thyrotoxicosis	No of patients with toxic nodular goitre	Mean initial dosage of neomercazole (mg daily)	Average maintenance dose in patients treated 5 mos or more (mg daily)	No of patients who discontinued treatment
Rapid (B M R to 0 in 2–8 weeks)	Small (est wt 25–40 g)	30	43 4 (*22–62*)	+29	29 (3 post operative recurrences)	1	22 6	4 (range *2–10*)	5 all in remission 2–7 mos
	Medium (est wt 40–60 g)	33	32 5 (*16–50*)	+32	29 (2 post operative recurrences)	4	27 0	7 (*[illegible]–20*)	3 (1 relapsed after 6 weeks 2 with toxic nodular goitre had operation)
	Large (est wt more than 70 g)	9	32 (*19–50*)	+54	9		32 5	14 (*10–15*)	
Slow (controlled after 3–6 mos	Small	11	61 5 (*35–72*)	+35	4 (2 post-operative recurrences)	7	30 0	18 (*6–30*)	1 defaulted
	Medium	5	35 (*28–47*)	+38	4	1	23 0	11 (*5–20*)	2 (1 defaulted 1 remission 4 mos)
	Large	2	56 and 23	+32 +2[illegible]	1	1	30	20	
Total		90			76	11			

ment The B M R was down to −11% in 1 patient and −14% in the 2 other patients, and the neck circumference increased by $^3/_4$ in in 2 of the patients The goitres became larger and firmer This goitrogenic reaction subsided rapidly when the dosage of neomercazole was reduced to 5 mg daily The 4th patient showed the most dramatic response of the whole series (see case 2 below) She received 40 mg of neomercazole daily Her B M R fell from +63% to +7% in twenty one days, during which her pulse rate dropped from 132 to 68 a minute This shows the importance of regular attendance during therapy

It appears from table III that the size of a goitre does not influence rapidity of response to neomercazole An equal percentage of large goitres is found in the two groups, and more medium sized goitres responded rapidly The type of goitre appears more significant Toxic nodular goitres account for half the slow responses and only for 7% of the group responding rapidly Elderly patients with small long-standing nodular goitres responded slowly on the whole It is also seen from this table that a higher maintenance dosage is required for large goitres and for all goitres showing slow response

Goitrogenic Reactions

Goitrogenic reactions were seen in 7 of the 120 patients 2 patients responded excessively quickly (see above) 1 patient showed an increase of her goitre after ten weeks' treatment with neomercazole 20 mg daily with a B M R of 0 her neck circumference increased by $^1/_2$ in Goitrogenic reactions developed after several months in 4 patients who were over-treated their B M R s at the time were −17% −11%, −11% and −13% and they were receiving 15 mg, 10 mg, 10 mg, and 25 mg, of neomercazole per day, respectively

1 patient had a very large goitre with primary thyrotoxicosis of three years' standing, and was ultimately operated on owing to pressure symptoms In each of the remaining 6 patients the thyroid returned to its previous size or less when the dose of neomercazole was reduced Over-treatment can take place without an increase in the size of the goitre 2 patients became almost myxœdematous with B M R.s of −30% and −18%, while taking neomercazole 15 mg daily, without any change in the size of their goitres

Most undue goitrogenic reactions can be avoided with neomercazole if the size of the goitre is watched carefully and the B M R kept between 0 and −10%

Decrease in Size of Goitre During Long continued Treatment

The thrill felt over superior or inferior thyroid arteries was the first sign to disappear—usually within one or two months, or even less At the same time pulsation diminished, the bruit became less loud, and then less blowing, until it finally disappeared In well controlled patients the gland became substantially smaller and softer

It is desirable to reduce the dose of neomercazole to the minimum compatible with adequate control throughout the period of treatment and to adjust the dose if an exacerbation of thyrotoxicosis develops 6 patients had a temporary exacerbation of toxicity after being controlled from six to nine months on a small dose of neomercazole After taking an increased amount of neomercazole for a few more months they were again controlled with the smaller dose

Of 90 patients 16 gave a history of increased psychological stress at the time they became thyrotoxic, and attributed the onset of their symptoms to their mental trauma 13 of these patients responded normally and became euthyroid in two to eight weeks, but 2 showed exacerbations with each emotional crisis and required larger dosage Both went into complete remission when their problems were solved, and discontinued treatment with neomercazole without recurrence The remaining 3 responded slowly

Auricular fibrillation was present in 6 patients treated without operation 2 of them had recurrent post-operative thyrotoxicosis, 1 having had two previous thyroidectomies The 4 other patients had old standing nodular goitre, and their average age was 64 The cardiac rhythm returned to normal in only 2 of these patients after long treatment

EYE SIGNS

Of the 90 patients followed up 37 had no eye signs 11 had only lid lag and 7 had malignant exophthalmos The rest all had some exophthalmos but no œdema, chemosis, or ocular muscle palsies Of the cases of malignant exophthalmos 2 were severe and progressive 2 were of long standing and 3 were mild 4 occurred was at least an hour before the cerebral studies were begun. At least twenty-five minutes between the first and second estimations was allowed for nitrous-oxide desaturation: two to three minutes before the second flow was begun 20–30 mg. of tolazoline in 0·8–1·2 ml. was injected intravenously, the exact amount being determined by the subjective and objective effects of a test dose administered the previous day. These included a feeling of fullness in the head, facial flushing, conjunctival injection, and lacrimation. In all other respects the conditions of the second estimation were identical with those of the first.

Results

The results of the studies are shown in the accompanying table.

Discussion

The results showed a striking and significant decrease in the cerebral vascular resistance (C.V.R.) after tolazoline, from a mean value of 2·0 to one of 1·5 ($t = 5·6$, $p < 0·01$); this was accompanied by increases in the mean cerebral blood-flow (C.B.F.) averaging 25%, which are also statistically significant (mean increase 11·7 ml. per 100 g. per minute, $t = 2·9$, $p < 0·05$). In 5 of the 6 patients the mean arterial blood-pressure (M.A.B.P.) fell slightly, the average decrease being 6%. The data are therefore sufficient to demonstrate that in this age-group with this order of dosage, and where no abnormal cerebral condition is present, appreciable and significant changes in the cerebral hæmodynamics follow the intravenous administration of tolazoline. These changes represent dilatation of the cerebral vessels (assuming the blood viscosity and the intracranial pressure to remain constant) and increase in mean cerebral blood-flow per unit weight of brain tissue.

RESULTS OF ESTIMATIONS OF CEREBRAL BLOOD-FLOW

Case no.	Sex	Age (yr.)	C.B.F.		M.A.B.P.		C.V.R.	
			C	E	C	E	C	E
1	F	29	38	47	75	70	2·0	1·5

Mean values		33	45	55	83	78	2·0	1·5

C.B.F., mean cerebral blood-flow in ml. of blood per 100 g. of brain per minute over ten-minute period of estimation.

M.A.B.P., mean arterial blood-pressure in mm. Hg over ten-minute period of estimation.

C.V.R., mean cerebral vascular resistance in mm. Hg per ml. of blood per 100 g. of brain per minute over ten-minute period of estimation.

C, control period.

E, period following intravenous injection of 20–30 mg. of tolazoline in 0·8–1·2 ml.

Hendrix et al. (1947) found that the skin-temperature of normal people and in vasospastic states rose with doses of tolazoline (0·5–1·0 mg. per kg. body-weight) considerably less than those required for sympatholysis or for adrenolysis, judged by diminution, loss, or reversal of the normal reflex and adrenaline pressor responses (2·0–3·5 mg. per kg. body-weight), and they suggested that this effect might be due to a histamine-like action on the vessels. The dosage in the present studies did not exceed 0·6 mg. per kg. body-weight, and a similar mechanism seems possible. The fact that sympathetic block has a negligible effect on the cerebral circulation (Harmel et al. 1949, Scheinberg 1950, Naffziger and Adams 1950) is compatible with this hypothesis. Further, histamine has been shown to be an effective cerebral vasodilator although it produces no concomitant increase in the mean cerebral blood-flow (Shenkin 1951, Alman et al. 1952). Both Alman et al. and Kety (1950) considered that the failure of histamine to increase the C.B.F. was most probably the result of the fall in arterial pressure produced by it. Shenkin (1951) analysed his figures regarding this point and found that the response of the C.B.F. varied with the degree of alteration in the head of pressure: where the fall in M.A.B.P. averaged 23%, the flow was not materially affected, whereas increases and decreases respectively occurred with falls in M.A.B.P. averaging 12% and 50%. Inspection of the present results shows a strikingly similar trend, and there proves to be a high degree of correlation between the changes in C.B.F. and those in M.A.B.P. ($r = 0·94$, $p < 0·01$).

Although there is no independent observation of C.V.R. measured as the ratio of M.A.B.P. to C.B.F., the changes in this value are more stable than those in the other two. This is in accord with the fact that the decreases in C.V.R. show the highest level of significance of the changes occurring after tolazoline, and suggests that the primary action of tolazoline is vasodilator, its effect on the C.B.F. being a function of its effect on the mean arterial pressure. It therefore seems reasonable, especially in view of the chemical and pharmacological resemblances between the substances, to regard the action of tolazoline on the cerebral circulation as essentially histamine-like but differing from that of histamine in that effective cerebral arterial pressure is *maintained with consequent increase in mean flow-rates.*

Further work is clearly needed to confirm and to extend these findings, especially as regards the effect of higher doses of tolazoline and to find whether a similar response takes place in acute and chronic cerebral ischæmia and where the blood-vessels are diseased. The experiments of Engel and the clinical reports referred to above suggest that, so far as acute ischæmia is concerned at least, tolazoline is likely to be effective. Such a result would be consistent with its frequently demonstrated efficacy in ischæmia and vasospasm elsewhere in the body. It may be noted, however, that Cholst et al. (1952) found by angioscotometry that the increase in calibre of the retinal arterioles which they consistently observed after intravenous tolazoline in normal people was much diminished in the presence of more than a moderate degree of retinal arteriosclerosis.

Pending both the results of further investigations along these lines and controlled clinical assessment of the practical value of tolazoline, we suggest that the use of tolazoline in the emergency treatment of cerebral embolism in young patients with rheumatic heart-disease is justified on theoretical grounds, since augmentation of the cerebral circulation by dilating the vessels and increasing the blood-flow through them is clearly the aim of such therapy.

Summary

The effect of tolazoline hydrochloride ('Priscol'; 2-benzyl-4 : 5-imidazoline hydrochloride) on the cerebral circulation has been determined by the nitrous-oxide method in 6 patients with mitral stenosis.

The results demonstrate significant changes in the cerebral hæmodynamic values after intravenous administration of tolazoline in doses of 20–30 mg.: a fall in the mean cerebral vascular resistance averaging about 25%; and an increase in the mean cerebral blood-flow per unit weight of brain tissue of a similar order.

The possible mode of action of tolazoline in this respect is discussed.

Modifications in the nitrous-oxide technique for estimating the cerebral blood-flow are described, including the sampling of cerebral venous blood through a cardiac catheter placed in the superior jugular bulb and the withdrawal of constant-rate blood samples by means of an electrically operated syringe device.

We wish to thank all those who have kindly assisted us in this study. We are especially indebted to Prof. A. F. Burstall and his staff, of the department of mechanical

This case shows that neomercazole is a potent anti-thyroid drug, since 15 mg daily produced almost complete myxœdema in four months It also illustrates the fact that *it is safer to reinforce clinical judgment* with B M R estimations In this case the serum cholesterol level did not rise above normal limits with over-treatment

Discussion

Neomercazole is probably hydrolysed to methimazole before it exerts its anti-thyroid action Its increased efficiency must be due to the maintenance of a steadier blood level produced by the slow release of methimazole

In assessing the activity of a new anti thyroid drug it often proves misleading to apply the results of experiments in rats, because of variations in response due to species differences For example, propylthiouracil is ten times more active and methylthiouracil *only half as* active in the rat as in man In the rat neomercazole did not prove superior to methimazole, it was slightly less goitrogenic weight for weight and was proportionally less effective in decreasing the consumption of oxygen by the rat

Stanley and Astwood (1947) advocate the testing of new anti thyroid drugs by their ability to inhibit the uptake of I^{131} by the normal human thyroid gland This method also proved misleading since it showed methimazole to have a potency a hundred times as great as that of thiouracil, which was not borne out in practice Neomercazole tested by this method inhibited the uptake of I^{131} more than methimazole did The blocked iodide uptake (Stanley and Astwood 1948) in thyrotoxic patients showed that 30 mg of neomercazole inhibited the synthesis of thyroxine completely in two thirds of the cases tested, whereas 50 mg was fully effective in all the tests made so far I^{131} tests do not take into account the cumulative properties of drugs and are therefore not a true measure of their clinical effectiveness

The objections to testing new anti thyroid drugs by treating thyrotoxic patients are the length of time required for clinical trials, *the great variation in the rate* of response to a full dose of anti thyroid drug, and the individual differences in the *minimal effective dose* The rate of clinical response is also affected by the amount of hormone stored in the *thyroid gland*, especially when iodine has been previously administered

These objections can be overcome if the final assessment of the anti thyroid drug is based on a large number of observations continued for a sufficiently *long time* Toxicity-rates can only be assessed after treating a large number of patients

A summary of the published reports on the use of methimazole is given below for comparison with results obtained with neomercazole

Stanley and Astwood (1949) who first tested methimazole, tried it on 30 patients but did not publish their results in detail, they gave 15 mg daily (personal communication to McGavack) Reveno and Rosenbaum (1950) gave as little as 6–15 mg daily but only 6 of their 18 patients seem not to have had previous treatment The rest were more or less already controlled with propylthiouracil when *methimazole* therapy was started, hence a maintenance dose could have been sufficient Their new *patients* improved on this dosage but were not completely euthyroid after three months

Beierwaltes (1950) tried methimazole in 9 patients and found the optimum initial dose to be 40 mg daily His average period of observation was two months, ranging from two weeks to six months, but his results are comparable with ours, where only 30 mg of neomercazole was given daily Taylor et al (1951) gave 30 mg or more to 23 *patients* Hallman and Bondy (1951) treated 35 patients and gave 20–60 mg, but most of their cases were *preoperative* and were treated for short periods None of these workers reported any toxic reactions—probably because of the smallness of dosage or the brevity of the trials

Bartels and Sjogren (1951) presented the first large series 100 patients given 30–50 mg daily Their maintenance dose of 2 5–5 0 mg daily is similar to ours They reported 6% of toxic reactions, mostly skin rashes, but 1 case of granulopenia was later seen by them With additional experience their toxicity rate was revised to 7 5% (Bartels 1952) Kendrick et al (1952) treated 32 patients with 30–45 mg daily and had 3 rashes Irwin et al (1952) treated 45 patients and decided on a dosage of 15 mg for small goitres, 30–45 mg for moderate goitres, and 60 mg for large goitres with severe toxicity The average dose administered was 38 8 mg Their incidence of toxic reactions was 6 6% For 1100 patients treated all over the U S A up to 1951 a toxicity-rate of 4 8% was cited (Hines 1951)

It seems that most of the larger series of patients treated with methimazole received a rather higher dosage than we find necessary with neomercazole The rate of response appears comparable to ours only in the series in which the larger dosage was used

The toxicity-rate of *methimazole seems definitely* related to the dosage (the most serious toxic reactions developed *in patients taking more than 40 mg daily*) and to the length of observation Where upwards of *30 mg daily* was *used*, all the workers reported toxic reactions except Hallman and Bondy (1951), most of whose patients had only 20 mg daily and short preoperative courses

For more than a year we have given 30 mg of neomercazole a day as an initial dosage without seeing any toxic reaction The reason for this becomes clear when one considers the molecular weights of the two drugs that of methimazole is 114, and that of neomercazole 186 The difference between these molecular weights is accounted for by the completely harmless and non toxic carbethoxy group Thus 30 mg of neomercazole contains only 18 5 mg of methimazole but is clinically as effective as 30–40 mg of methimazole The highest dosage of neomercazole found necessary in our series, 45 mg *contains 27 4 mg of methimazole*—barely the average dose of methimazole administered by other workers

4 cases of agranulocytosis have followed the use of methimazole (Croke and Berry 1952, Bartels 1952), and theoretically the possibility of this complication exists with neomercazole, but it is extremely unlikely in view of the small amount of the potentially toxic methimazole used when neomercazole is administered Probably neomercazole will have a toxicity rate only a fraction of that of methimazole, with a weight for weight efficiency which promises to be somewhat higher

The final remission-rate and total duration of treatment with neomercazole will have to be assessed when more patients have finished their course The correlation between intensity of treatment and permanent cure is not yet established

Astwood (1949) thinks that a higher proportion of permanent remissions is obtained when the initial dose is continued until the signs of early myxœdema appear and a maintenance dose given which will keep the patient in a state of normal or slightly subnormal thyroid function McGavack (1951), on the other hand, advocates *keeping the* B M R *between* +5% and +15% and avoiding the risk of goitrogenic reactions One of the objections *to definitive* anti thyroid therapy is the possible development of adenomas in the treated gland, and the remote possibility *of future malignant* changes Both these dangers are greatly enhanced in the over-treated thyroid, when the thyrotrophic hormone of the pituitary gland exerts its unopposed influence *In our* treatment with neomercazole we have therefore preferred to reduce the dosage as soon as the patient became euthyroid We have tried to avoid over treatment by checking the required dosage by regular B M R estimations The usual objections to the B M R test *do not* apply to patients who follow a prolonged course of medical treatment and *thus become* accustomed to the performance of the test, especially if the tests and the entire management of the case are personally supervised by the same physician of man's greatest activity, that once established it tends to persist, and that the risk of perforation remains even in old age.

MORTALITY-RATE

The mortality-rate of an operation is the yardstick by which its immediate success or failure is measured. In this series of 206 perforations there were 13 deaths—a mortality-rate of 6·3%. This accords with that of other series recently published (Chamberlain 1951, Heslop 1951, Beattie 1951), which show a mortality-rate of about 8% and mark an important improvement that is agreed all over the country. The recent study of this subject by Avery Jones et al. (1950) attributes this lessened mortality to the use of antibiotics and to better techniques in anæsthesia. In the present series none of the 7 women died, and in 55 consecutive cases all the patients recovered, including 4 who had suffered perforation for more than twelve hours, and 3 for more than twenty-four hours. Several factors appear to influence the immediate mortality-rate.

Time factor.—It is generally agreed that delay in operating on perforations tends to increase the mortality-rate. It is satisfactory to report that 164 patients (80%) were operated on within twelve hours of perforation, with 5 deaths—a mortality-rate of 3%. With a delay of twelve to twenty-four hours 3 of 17 patients (18%) died. With delay of over twenty-four hours 4 of 10 patients died—a mortality-rate of 40%. In 15 cases the exact times are not recorded, and 1 of the patients died. These figures show the importance of early operation.

Age factor.—As might be expected, a significant rise in the mortality-rate accompanies age, particularly after 60:

Under the age of 40, 1 of 89 patients died (mortality-rate 1%).

Between the ages of 40 and 59, 6 of 84 patients died (mortality-rate 7%).

Of those aged 60 or more, 6 of 33 patients died (mortality-rate 18%).

These figures illustrate the increasing risk which advancing years add to perforations.

Site of ulcer.—There were 160 duodenal perforations with 7 deaths (mortality-rate 4·4%). Of 43 patients with gastric perforation 5 died, and of 3 with stomal perforation 1 died. The figures of gastric and stomal ulcers are too few to be statistically significant, but they suggest that there is a greater risk with gastric and stomal perforations. This is perhaps due to the fact that such patients are often ill-nourished and debilitated; their perforations are sometimes difficult to suture, particularly when the ulcer is chronic; they are usually more shocked than patients with duodenal perforation; and there is usually a greater degree of peritoneal soiling because of the wider spread of acid gastric contents.

Type of ulcer.—Perhaps the most important factor affecting the immediate mortality-rate is the proportion of chronic ulcers in any series of perforations. In this series there were 119 patients with perforated acute ulcer, and none of these died. In contrast there were 87 patients with perforated chronic ulcer, and 13 of these died. This reveals the important fact that the total mortality-rate of 6% was wholly attributable to the chronic ulcers, and that as a group their mortality-rate was about 15%.

REMOTE RESULTS

In assessing the remote results of our 206 cases we have to exclude the 13 patients who died while in hospital and 4 others whom we failed to trace. This leaves 189. Of this number 8 have since died: 5 from intercurrent disease; and 3 from conditions directly associated with the original peptic ulcer—namely, abscess of the lung following subphrenic abscess, reperforation of a mid-gastric ulcer in an old man, and an acute duodenal-ulcer hæmorrhage during an attack of infective hepatitis. These 3 patients all died at home from three to five months after leaving hospital, and should properly be regarded as an increment to the mortality of perforated ulcer. We have therefore 181 survivors for the completion of this review. The remote results have been classified on a clinical or symptomatic basis into three main groups:

(1) *Satisfactory cases.*—This includes all who express themselves as "perfectly well." They are symptom-free and working regularly.

(2) *Moderately well.*—This group comprises all those who, though admitting to a mild degree of dyspepsia at times, have not required medical care and have not lost work.

(3) *Poor results.*—This covers all who have had recurrent ulcer symptoms, who have had further medical or surgical treatment, and who have lost a considerable amount of work.

Table III shows the remote results in 181 survivors after perforated peptic ulcer. These results differ a little from a former series (Gilmour and Saint 1932), in which the satisfactory cases were 38·6%, fair results 25%, and poor results 36·4% after five years. Grey Turner (1931) found that 50% of his patients with sutured perforations had further symptoms; and Illingworth et al. (1946) reported 40% relapse in a year, rising to 70% at the end of five years. The present analysis reveals again the striking tendency towards further relapse, which 50% of all the patients undergo, and calls for further consideration.

TABLE III—THE REMOTE RESULTS IN 181 SURVIVORS AFTER PERFORATED PEPTIC ULCER

Results	Duodenal cases	Gastric cases	Total
Satisfactory ..	52 (*36%*)	10 (*29%*)	62 (*35%*)
Moderate ..	25 (*17%*)	3 (*9%*)	28 (*16%*)
Poor	68 (*47%*)	21 (*62%*)	89 (*50%*)
Total	145	34	179

There were also two stomal ulcers which as such were poor results.

PROGNOSIS

Method of Assessment

In a study of this kind it is not enough to recognise that late results may be good, moderately good, or poor, or even to know the percentage of such results. We desire to know, if possible, which ulcer patient will probably remain well after recovering from his perforation, and which will probably relapse. The problem is therefore to establish a rational basis for such prognosis, so that the patient may be given the best advice and treatment as early as possible. To do this we have to rely on ascertainable facts, such as the preoperative history and the type of ulcer. If it can be shown that such are in any respect constant in each of our three groups of late results, and that there is a relationship between the clinical type and the grade of late result, something tangible will have emerged to aid us in making such a prognosis.

Clinical Types of Perforations

The preoperative clinical histories show that perforations may be classified into two main groups:

(1) Those which occur in a first acute attack of peptic ulceration, acute ulcers.

(2) Those which complicate an acute exacerbation of a known chronic peptic ulcer.

In group 1 there is either no previous history of dyspepsia whatever, or the history of indigestion is so vague that *peptic ulceration* is neither suspected nor diagnosed. Pain is not a feature in the history of these mild gastric disorders.

In group 2 there is always a record of recurrent bouts of painful dyspepsia, marked in many instances by which it was reduced to 10 mg twice daily, or even 5 mg twice daily

Case 1 —A woman aged 29, with a three months' history, had a large hyperplastic gland B M R +55% Receiving 30 mg neomercazole daily for 9 weeks, she became symptom free and gained 9 lb The dosage was then reduced to 20 mg daily, given with thyroid sicc As she was two months pregnant and the thyroid was still enlarged subtotal thyroidectomy was advised and was performed a month later The gland (82 g) showed typical diffuse hyperplasia but some colloid formation At operation the gland was firm with no undue vascularity and stripped readily from its fascial capsule There was no postoperative reaction

Case 2 —A woman of 58 had for 3 months had asthenia, anorexia, and palpitation Her thyroid was not visible or palpable but her B M R was +35%, her pulse rate was 160, and she had lost 46 lb She was given neomercazole 30 mg daily A fortnight later her husband had a fatal coronary occlusion, but after another 2 weeks her B M R was +19%, her pulse rate was 96 and she felt well At the end of 6 weeks, dosage was reduced to 20 mg daily At the end of 3 months, with B M R −13%, she had put on 11 lb weight and felt well After another month, the supply of neomercazole ran out, but she has kept well on mild sedation

Case 3 —A woman of 46 had developed her symptoms some 6 months after a hysterectomy In the next 6 months she had been given iodine and sedation but she had lost 21 lb and her thyroid had enlarged She had then received methyl thiouracil and 4 weeks later developed agranulocytosis with a temperature of 105°F and ulcerated throat This was quickly controlled but her B M R was +30% I gave her neomercazole 20 mg daily for 10 days and then 30 mg daily After 4 weeks her weight had increased by 8 lb and her B M R was −3% Dosage was then reduced to 10 mg daily, and 6 weeks later her B M R was +10%, but as she was symptom free the same dosage was maintained After another 6 weeks her B M.R was −17%, her thyroid was apparently normal, she had put on 7 lb weight, and she was symptom free After 2 further months on mild sedation she was still well During treatment with neomercazole her leucocyte count rose from 7400 (neutrophils 62%) to 13,000 (neutrophils 67%)

Case 4 —A man, aged 32, had become ill 5 years previously when his B M R was +65% After 3 months his condition had improved but in view of the large, very vascular thyroid and his poor physical state, the surgeon refused to operate After a further 9 months the surgeon again refused For another 2–3 years he was in poor health and 6 months before I saw him his B M R was +41% When given methyl thiouracil in large doses he developed a reaction with fever, vomiting, and increased asthenia As the thyroid had enlarged very much, operation was again refused, and he was given large doses of iodine When I first saw him his condition was parlous he had a very large hard vascular thyroid his pulse rate was 140, and he could not walk Treatment with propyl thiouracil reduced the leucocytes to 4900 with 58% neutrophils He was then given neomercazole 30 mg daily, and in 4 weeks felt a new man and had gained 5 lb leucocytes 6350 but neutrophils only 48% The dosage of neomercazole was increased to 45 mg daily, and in 4 weeks he gained 4 lb pulse rate 100, leucocytes 5350 (neutrophils 85%), B M R +21% The thyroid was still very large but its vascularity seemed less After a further month (15 mg daily for 2 weeks and then 30 mg for 2 weeks) he entered hospital and was given iodine for 5 days prior to operation This was carried out without any difficulty and very little blood loss The gland was large but moderately firm, it was easily handled, and the tissue planes stripped readily The whole right lobe, the isthmus, and the greater part of the left lobe was removed the tissue removed weighed 210 g and its microscopical appearance was that of a colloid goitre with small areas of hyperplasia There was no postoperative reaction and in 3 months he had put on a further 7 lb and had resumed work after 5 years invalidism

Case 5 —A woman of 36 Her illness had an acute onset in October 1951 when her B M R was +96% She received large doses of methyl thiouracil for 2 months and after 3 months showed hypothyroidism and a greatly enlarged thyroid At this time a bout of alcoholism necessitated 4 weeks institutional treatment at the end of which her B.M R was +26% and her pulse rate 108 She was then given methyl thiouracil 0 3 g daily with thyroid sicc gr ½ daily but after 3 months she had not settled, B M R +27% After 4 weeks' treatment with neomercazole 30 mg daily her B M R was +5% and her pulse rate 70 She had gained 6 lb, had lost the puffiness of her face, and felt like her old self After another 4 weeks she was symptom free and the thyroid had receded to almost normal proportions As the supply of neomercazole was now exhausted she was given methyl thiouracil 0 2 g with thyroid sicc gr. ½ daily, and has maintained her good condition for a further 3 months

Case 6 —A woman of 47 with symptoms for 12 months Methyl thiouracil, tried on four occasions, had always caused a toxic reaction with swelling of face and hands Her blood pressure was 220/90 and she was showing signs of congestive cardiac failure B M R +20% Neomercazole, 30 mg daily, was commenced, and in two weeks her B M R had fallen to −12%, her weight had risen by 9 lb, and she was symptom free As her thyroid had been enlarged for some years, operation was advised and performed some 2 weeks later by a colleague, who commented on the ease of operation and the slight blood-loss The tissue removed showed many vesicles containing colloid with considerable hyperplasia She made a rapid recovery

Case 7 —A man of 31 with symptoms since October, 1951 He had been given methyl thiouracil and iodine for 7 months with marked improvement but had relapsed within 8 weeks of ceasing treatment, when his B M R was +28% and his pulse rate 140 He had a large adenomatous thyroid After 8 weeks on neomercazole 30 mg daily, his B M R was +10%, and his pulse rate 80 Total thyroidectomy was then performed without difficulty or blood loss The gland weighed 175 g and showed colloid adenomata with hyperplasia in the surrounding gland tissue There was no postoperative reaction

Case 8 —A woman of 47 had noticed her thyroid enlarging for 2 years, and in the last 6 months had lost 12 lb B M R +47% Toxic symptoms were alleviated by methyl thiouracil but the thyroid grew rapidly and seemed very vascular Although the dose of methyl thiouracil was reduced and she was given thyroid sicc the gland enlarged still further and her pulse rate was 108 B M R −1% She was then given neomercazole 15 mg daily, and after 8 weeks was so much improved that operation was undertaken Total thyroidectomy was performed with removal of a very large gland which was firm and easily handled without any undue bleeding and fascial planes were clear

Case 9 —A woman of 65 gave a 4 years' history of weight loss with increasing asthenia For the last 3 months she had been in hospital with fibrillation For many years she had had a small adenoma in the left lobe of the thyroid B M R +15% Despite a leucocyte count of 3400 (neutrophils 34%) she was given methyl thiouracil and within a week had agranulocytosis though without febrile reaction With treatment, the leucocytes rose in 2 weeks to 6400 (neutrophils 68%) She was then referred for operation, but because of a low hippuric acid excretion (63% of normal), her poor physical condition which suggested adrenal deficiency, and the recent agranulocytosis neomercazole was advised, 30 mg daily For 3 weeks she seemed to be much the same but in the next 3 weeks she improved rapidly and though she still had a slow fibrillation total thyroidectomy was performed without any trouble There was a degenerating cysto adenoma in the left lobe of the thyroid with diffuse generalised hyperplasia in the rest of the gland tissue There was postoperative aggravation of the fibrillation which was not controlled for some 3–4 weeks She has put on weight and has resumed her ordinary activities

I should mention that ancillary treatment was given in all my cases for example, phenobarbitone was prescribed as a sedative, and iron where there was anæmia The patients received vitamin B, or, in cases with much weight-loss, mixed vitamin compounds

CONCLUSION

Experience in this small number of cases suggests that 'Neo Mercazole' is superior to any of the thiouracil compounds, not only for control of thyrotoxicosis but also for reducing the vascularity of the gland before operation In the dosages employed it reduces the basal metabolic rate more slowly than the thiouracils but it does not induce or increase thyroid hyperplasia and it does not interfere with the leucocytes It therefore appears to be a safer remedy and there is reason to treatment commonly fails with cases of chronic ulcer. The larger perforation and the rigid margin of the ulcer make closure by adhesions more difficult to achieve, and delay *in operating in these cases can only increase* the hazard. Further, when adhesion does occur between the base of a chronic ulcer and the liver, there may be a risk of converting a perforating into a penetrating ulcer. *On theoretical grounds the method seems to be more* suitable for the small acute-ulcer-perforation, where the peritoneal reaction sometimes leads to sealing off, which is facilitated by the flexibility and mobility of the viscera. *Indeed these cases are probably responsible for the* measure of success which has attended this mode of therapy. Its value in the presence of associated conditions, such as coronary and pulmonary disease, and in neglected cases, *for which it was first proposed by* Wangensteen (1935), is freely acknowledged. It might also be suitable for patients with a perforation that have to travel many miles to hospital, who might first have the stomach contents aspirated.

Primary partial gastrectomy for perforation has been practised in Continental clinics for fully thirty years and Nuboer (1951) draws attention to the great possibilities of this operation in the hands of the skilled surgeon. A mortality-rate of 3·8% in 131 cases is eminently satisfactory, especially when it is remembered that this procedure deals not only with the perforation but also with the ulcer and its possible sequelæ. It is pertinent to point out, however, that in using this operation as the standard treatment for all perforations Nuboer includes the relatively acute-ulcer cases with the chronic ulcers. The present investigation has shown that the acute-ulcer cases number 64% of the total, and that less than 10% of them have required further surgery within the five years; they also include the youngest patients. For these reasons such a drastic operation in an acute-ulcer case seems unnecessary, particularly when these cases can be dealt with safely by simple suture, and any evidence of recurrence can be treated by a planned operation. It is in the treatment of perforated chronic ulcer that primary partial gastrectomy may have its proper place, if it can be proved to be associated with a lower mortality-rate and morbidity-rate than simple suture. This experiment seems well worthy of trial; and if, as Nuboer says, the cases are easier to do in the presence of œdematous tissue planes than some planned operations for chronic ulcer, the patient should benefit from such timely intervention.

When any doubt exists about the practicability of the operation, the surgeon can revert to simple suture and leave his resection to a later date. Conversely, when he finds a large chronic ulcer whose rigid walls will not approximate, when there is reason to believe the ulcer is carcinomatous, or when there is an associated hæmorrhage, the surgeon may profitably proceed with the partial gastrectomy. Success will depend on the wise selection of patients, and *gastrectomy should be considered only* in those patients who are deemed fit enough to withstand the operation and exhibit no signs of peritonitis. A more serious attempt is needed to reach an accurate preoperative diagnosis of the type of ulcer involved in the perforation, so that adequate measures may be invoked to deal with it.

SUMMARY

Of 206 acute perforated *peptic ulcers 119 (58%)* were found to be acute ulcers and 87 (42%) chronic ulcers.

Treatment consisted in laparotomy and simple suture of the perforation.

The over-all mortality-rate was 6·3%. All 13 deaths were in the group of 87 cases of perforated chronic ulcer; in this group the mortality-rate was 15%, compared with nil in the 119 cases of perforated acute ulcer.

My thanks are due to Mr. J. D. Rose and to Mr. J. D. T. Jones, successively my assistant surgeons, and to Mr. C. J. Evans, Mr. K. Turnbull, Mr. F. I. Herbert, Mr. I. Marks, and Mr. W. G. Ferguson, who have been my surgical registrars during the period covered by this paper. The successful treatment of these emergency cases is largely due to their efforts, and to the nursing skill of Sisters Mackie, Atkinson, and Burke and their nurses. I must also acknowledge the assistance of Mr. W. G. Ferguson in the conduct of the "follow-up," and of Mr. H. Campbell, statistician in the department of *industrial health in the medical school, who reviewed the* tables and the conclusions based upon them. Finally, I am greatly indebted to Mr. J. D. T. Jones and to Mr. H. J. B. Atkins for much helpful advice and criticism in the preparation of this paper.

TREATMENT OF THYROTOXICOSIS WITH 'NEO MERCAZOLE' (2-CARBETHOXYTHIO-1-METHYLGLYOXALINE) *

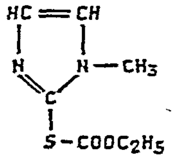
REPORT OF 120 CASES

DEBORAH DONIACH
M.D. Lond.
THYROID RESEARCH ASSISTANT, ROYAL FREE HOSPITAL, LONDON

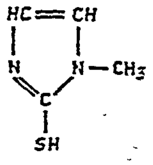
This paper presents the results of a clinical evaluation of the anti-thyroid compound 2-carbethoxythio-1-methylglyoxaline ('Neo Mercazole') in the treatment of thyrotoxicosis. In 30 cases it was used to prepare patients for operation, and in 90 cases it was used as a definitive form of treatment. In these observations, made between April, 1951, and February, 1953, no toxic reactions were seen.

The preliminary experiments on animals were reported by Lawson et al. (1951), and the first few cases by Lawson and Barry (1951).

Neomercazole, formerly called C.G.1, is a modification of 1-methyl-2-mercaptoimidazole (methimazole; 'Mercazole' in Great Britain, 'Tapazole' in the United States) (Stanley and Astwood 1949), which has been increasingly used in the U.S.A. since 1948 as an alternative to thiouracil derivatives. Methimazole has a tenfold anti-thyroid potency and a toxicity-rate of about half that of the older drugs. Neomercazole was synthesised by Lawson et al. (1951) in the hope of further reducing the toxicity-rate, which for methimazole is still considered by most workers to be 3–6%.



Neomercazole



Methimazole

The theoretical advantage of neomercazole over methimazole is that in neomercazole the active part of the molecule is blocked by a carbethoxy group: methimazole is probably released gradually by hydrolysis and the thyroid receives a more constant supply of the active thiol group. Thus a smaller quantity of the active drug may suffice.

---

* This investigation was supported by a grant from the endowment funds of the Royal Free Hospital. The author's thanks are also due to the research grants committee of the Middlesex Hospital, London, W.1.

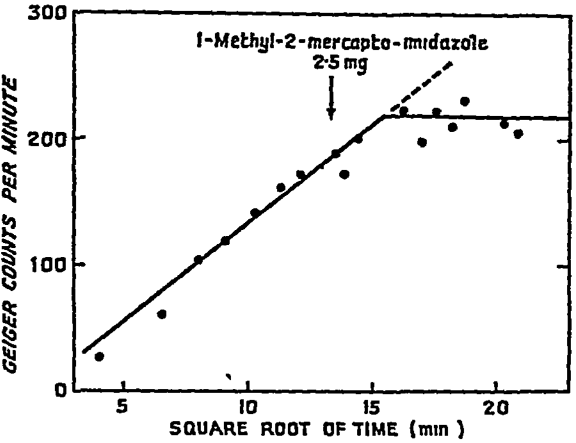


Fig 3—Effect of 2 5 mg of 1-methyl 2-mercapto-imidazole on accumulation gradient in thyroid gland

below 2 5 mg was very transient, whereas fig 2 shows a fairly prolonged effect due to 0 5 mg of C G 1 It has always been suggested that the former drug be taken in frequent divided doses because of the transient nature of the inhibition produced

Our own limited experience of the clinical use of these drugs suggests that they are both effective anti thyroid agents, but considerable caution should be exercised in the transfer of the results of potency trials of this type to the clinical field of therapy These radioactive-iodine tests suggest a potency possibly fifty times greater than that of methyl thiouracil This does not imply, however, that the therapeutic dose is correspondingly low Most observers now agree that 1 methyl-2-mercapto-imidazole has to be administered in very much higher dosage than was originally assumed to be necessary, and weight for weight, it is probably about ten times as active clinically as methyl thiouracil In the same way, where C G 1 is being used extensively, the dose necessary to achieve adequate control is higher than that first recommended (Lawson and Barry 1951)

The role of anti-thyroid drugs in the management of hyperthyroidism is now clearly defined, and, with the increasing availability of radioactive iodine for the therapy of thyrotoxicosis, their use is predominantly in the treatment of young patients and in the preliminary preparation of the patient for operation Both methyl thiouracil and propyl thiouracil are satisfactory members of the group, and to compete with them a new drug must have definite advantages A lower absolute dose is of little value in itself unless it can be shown to be accompanied by fewer undesirable side effects Dunlop and Rolland (1950) found that undesirable reactions to methyl thiouracil, sufficient to necessitate the abandonment of treatment, occurred in 7% of cases, and Iversen (1951), using the same drug, had to discontinue treatment in over 10% of his patients In contrast, most workers with 1-methyl-2 mercapto-imidazole have reported a low incidence of toxic reactions, but Stone Petit, and Starr (1952) have found that, when it is used in effective clinical dosage, its toxicity is somewhat higher than that of propyl thiouracil, and they had toxic reactions in 8 out of 29 patients (27%), two of the reactions being serious

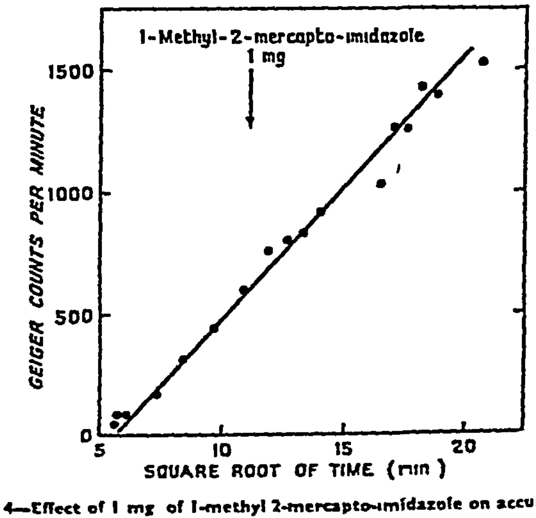

Fig 4—Effect of 1 mg of 1-methyl 2-mercapto-imidazole on accumulation gradient in thyroid gland

Very large numbers of patients will have to be treated with the new drugs before statistically valid comparisons can be made

SUMMARY

The anti-thyroid activity of 2 carbethoxythio 1 methylglyoxaline (C G 1) and that of 1-methyl 2 mercapto imidazole have been compared by the technique of Stanley and Astwood (1947)

Both drugs are fully effective in a single dose of 2 5 mg, but 2 carbethoxythio 1 methylglyoxaline appears to be consistently slightly more potent than 1-methyl 2 mercapto-imidazole in doses below this level

The present rôle of the anti thyroid drugs in therapy is briefly discussed Considerably higher doses of the new compounds are required in clinical practice than was originally recommended

We are grateful to Prof C Rimington for the supply of C G 1, and to Prof E J Wayne for his interest in these observations We should like to thank Miss Lorna Mann for her technical assistance

CONSULTANT PATHOLOGIST

LEO GILCHRIST
M D Belf, M R C P, D P M
CONSULTANT PHYSICIAN

FARNBOROUGH HOSPITAL, KENT

THE term "cryoglobulin" (Lerner and Watson 1947) describes a protein which is precipitated from serum or plasma on cooling and redissolves on warming Cases have been described by Shapiro and Wertheimer (1946), Hill et al (1949), Rorvic (1950), Blades (1951), Luckey et al (1951), and McFarlane and Dovey (1952) Most of these were cases of multiple myelomata, but the anomalous protein has occasionally been found in nephrosis (Wertheimer and Stein 1944), endocarditis (Lerner and Watson 1947), polyarteritis nodosa (Lepow et al 1949), and infective arthritis (Rorvic 1950)

In the case to be described here cryoglobulinæmia developed while the patient was under treatment

Two tests, which are commonly used in the United States but not in this country, have been used in this laboratory for some time In both of these the globulins are precipitated and estimated turbidimetrically de la Huerga and Popper (1950) use as reagent a saline ammonium sulphate solution, and Kunkel (1947) a barbitone and zinc sulphate solution Both are specific precipitants for γ globulins, but the Popper reagent also precipitates fibrinogen and consequently should be used only on serum The normal values are Popper 0-6 units and Kunkel 2-12 units

TABLE II—ANALYSIS OF 30 CASES TREATED PREOPERATIVELY

Mode of response to neomercazole	Size of goitre	No. of patients	Average age and age range (yr.)	Average initial B.M.R.	No. of patients with primary thyrotoxicosis	No. of patients with toxic nodular goitre	Mean dosage of neomercazole (mg. daily)
Good clinical response (mean B.M.R. fall = 1·5% per day)	Small (mean wt. 30·3 g.)	3	37 *(32–44)*	+30%	3	..	25
	Medium (mean wt. 48 g.)	10	40·7 *(22–51)*	+47%	5 (1 postoperative recurrence)	5	23
	Large (av. wt. 109 g.)	8	48 *(25–64)*	+37%	3	5	26
Slow response (mean B.M.R. fall = 0·3% per day)	Small (av. wt. 26 g.)	6	49 *(40–65)*	+33%	4 (1 postoperative recurrence)	2	23·3
	Medium (wt. not recorded)	2	49 *(32 and 66)*	+46%	1	1	40 and 20
	Large (wt. 102 g.)	1	43	+21%	..	1	20
Total	..	30	..	..	16	14	

Results

PREOPERATIVE MEDICATION

The preoperative group included 14 patients with toxic nodular goitre and 16 with primary thyrotoxicosis (2 having had previous thyroidectomies). Table II shows their response. The mean percentage in B.M.R. fall was calculated by taking the difference between initial B.M.R. and last preoperative B.M.R. and dividing by the number of days' treatment. For the 21 patients who responded well clinically the mean fall in B.M.R. was 1·5% per day. The 9 remaining patients showed a slow clinical response, and their B.M.R. fell by 0·3% a day. The two groups contained the same proportion of toxic nodular goitres, and there was no significant difference in the amount of neomercazole administered or in the initial B.M.R. However, there were more small goitres and the patients were older in the group showing slow response. Dosage was low in the first cases treated, and some patients were operated on while their B.M.R. was still between +10% and +25%.

Four of the patients with toxic nodular goitre were referred from the cardiac department—2 with auricular fibrillation and early cardiac failure, and 2 with hypertension. All were successfully prepared for operation, but 2 of them responded slowly and required both neomercazole and supportive treatment for three months.

None of the goitres enlarged during the short course of treatment. At operation the goitres were not particularly friable or more difficult to remove than in patients prepared with iodine only. Histologically the glands showed great variations and on the whole looked active.

DEFINITIVE TREATMENT

90 patients were treated medically with neomercazole for periods varying from a few weeks to twenty-one months. 76 patients had Graves's disease, including 7 postoperative recurrences; 14 patients with toxic nodular goitre received curative treatment for various reasons; 6 refused operation; 2 had ocular muscle palsies; 4 were old and hypertensive, with a small goitre; and 2 were well controlled with neomercazole but were ultimately operated on because of deviation of the trachea at the thoracic inlet, present before operation.

So far 6 patients have terminated their course of treatment and have remained well from two to seven months. In 2 other cases treatment was stopped, but symptoms recurred and neomercazole therapy had to be resumed:

The first patient was a postoperative recurrent thyrotoxic who had been well controlled for twelve months and had a maintenance dose of 6 mg. daily and a B.M.R. of −18%. Symptoms recurred within six weeks, with a rise of B.M.R. to +14%.

The other was a patient who had had a large nodular goitre for forty years with signs of toxicity for two years and auricular fibrillation when first seen. She refused operation and was treated with neomercazole for eighteen months, being well controlled on 10 mg. daily. Symptoms and signs returned within two months of ceasing treatment.

Table III shows the responses in these 90 patients: 72 showed a rapid clinical response and became euthyroid in two to eight weeks. Included are the results in 8 patients previously treated with methythiouracil, who all remained well when neomercazole 2·5 mg. was substituted for every 25 mg. of methylthiouracil. In mild cases with small goitres the B.M.R. usually returned to normal in two to four weeks; more severe cases took four to eight weeks to become euthyroid. 2 mild cases gave a delayed response due to previous saturation with Lugol's iodine.

Slow Response

18 cases responded slowly and were finally controlled after three to six months except for the 2 patients who defaulted. Here again, of the small goitres a large proportion were in elderly patients, of whom 7 had long-standing nodular goitres.

In 3 patients insufficient dosage was probably responsible for the delay in response. One of these, a postoperative recurrent thyrotoxic, was ordered 30 mg. a day but took the neomercazole irregularly to an estimated average of 10–12 mg. daily. She was controlled as soon as she was persuaded to take the full dose. 2 other patients were given 16 mg. and 20 mg. daily, a dose believed to be adequate early in the trial but now proved to be insufficient as an initial dose in severe cases. In 3 patients excessive psychological stress may have retarded the response to neomercazole, but 1 of these had only 20 mg. daily.

4 patients responded slowly to 30 mg. daily though they were straightforward primary thyrotoxics of average severity. An iodide trap test (Stanley and Astwood 1948) done on 1 of these showed that neomercazole 50 mg. blocked the synthesis of thyroxine completely, suggesting normal uptake of neomercazole by the thyroid. This patient responded rapidly when the dose was increased to 45 mg. daily. Possibly the patients who respond slowly to an average dose of neomercazole detoxicate or excrete it more rapidly and therefore need a larger amount to maintain a sufficient blood level.

Rapid Response

In contrast to these slow responses 4 of our patients reacted to neomercazole with unexpected rapidity. The B.M.R. (initially +49%, +34%, and +42%) returned to normal in two weeks on 30 mg. daily in 3 cases. After four weeks on this dose they showed signs of over-treat-

New Inventions

DOUBLE SUTURE-PASSER

SURGEONS brought up in the tradition of Ernest Miles, who use thread ligatures passed with his suture-passer, will appreciate the advantage of being able to pass a pair of parallel sutures with a single manipulation

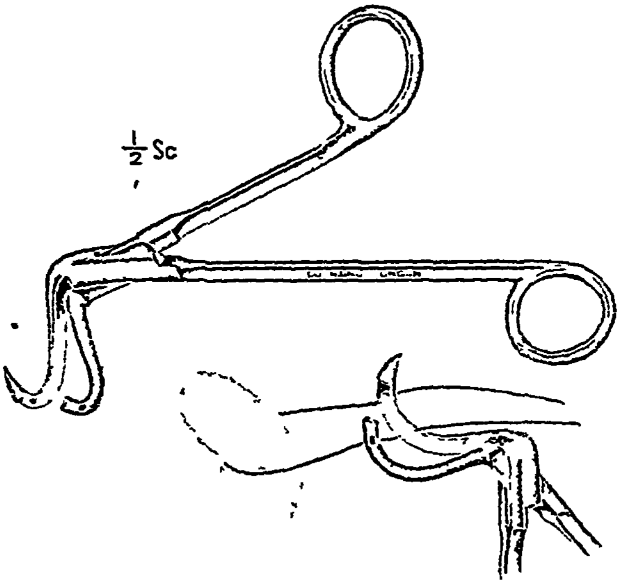

Fig 1—The double suture-passer After the instrument has been passed, the blades are opened to enable the thread to be hooked out by the finger

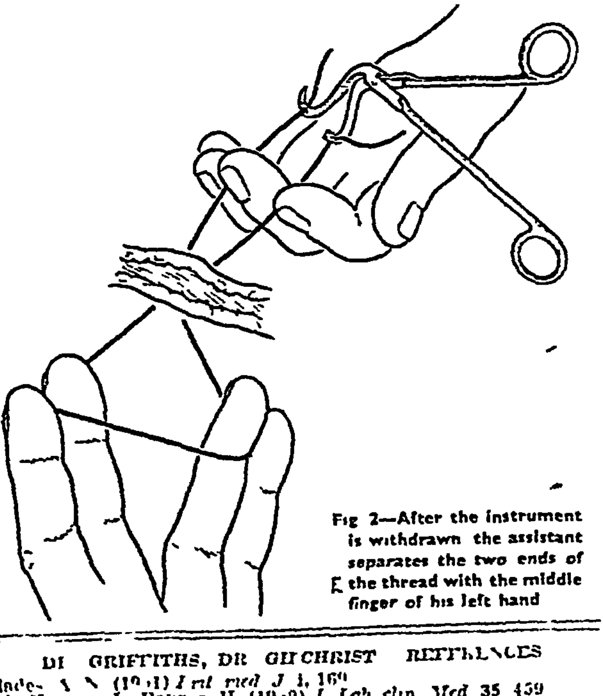

Fig 2—After the instrument is withdrawn the assistant separates the two ends of the thread with the middle finger of his left hand

The instrument here illustrated (fig 1) is a combination of aneurysm needle and Miles suture-passer, set on the handles of a Gillies needle-holder It is threaded with the blades closed, so that the double eye lies at the middle of the thread which trails to the right over the handle After it has been passed through the tissue (mesentery omentum or blood-vessel) which is to be doubly ligated the jaws are opened thus stretching the centre of the thread so that it can be hooked out by the operator's left middle finger Then the instrument is withdrawn the blades being *almost closed as they pass through the* hole in the tissue and opened again so that the assistant may separate the two threads with the middle finger of his left hand (fig 2) Finally the operator then cuts the centre of the thread, leaving two parallel ligatures

In major gastric and intestinal resections this instrument reduces the number of manipulations with the suture-passer, and by ensuring that both sutures pass through the same hole it lessens the risk of bleeding Also it saves much time

It is made by Down Brothers and Mayer & Phelps

Mitral Valvotomy

ON March 19 Dr MAURICE CAMPBELL, discussing the Selection of Patients for Mitral Valvotomy and the Results, said that fifty years ago Lauder Brunton had suggested the surgical relief of mitral stenosis and had carried out some experiments on animals and in the necropsy room, but he could not find a surgeon who was interested More than twenty five years ago the first unsuccessful attempts were made, though the approach through the left auricle by Allan and the use of the finger for splitting the valve introduced by Souttar were valuable steps

Dr Campbell's figures were based on the first 100 patients operated on by Mr R C Brock and seen by Dr C G Baker, Dr Paul Wood and himself, with 50 others operated on since then Nearly all these patients were seriously disabled before operation After operation two thirds of them had returned to work and were often able to walk two miles or more, in many cases the improvement was dramatic Nearly all the patients had been followed for more than a year, and the first 50 for two to four years Mitral regurgitation did not follow a successful operation, but the murmurs generally remained, although they might disappear completely, as might the murmur of pulmonary regurgitation

There were 13 deaths in the first 100, but since the first 20 the mortality has fallen to 8% It was twice as high in those with auricular fibrillation as in those with normal rhythm Of the survivors 1 in about 5 could not be helped or was only moderately improved, but the two thirds obtained great help and could lead reasonably full lives It was soon realised that the young patients with signs and symptoms of pulmonary congestion, and often without much enlargement of the heart, were greatly improved Further experience showed that success could also be gained in older patients with larger hearts and in a wider variety of cases including patients who had had emboli or congestive right sided heart failure

The greatest disappointment of the operation was the frequency with which auricular fibrillation followed it Often this was paroxysmal and stopped spontaneously or could be stopped with quinidine, but in too many it remained established In the only 2 deaths that Dr Campbell himself knew of it was a factor the 1st patient died suddenly and unexpectedly a few hours after normal rhythm had been restored with quinidine nineteen months after a successful operation, the 2nd died from a large pulmonary embolus due to venous thrombosis in

patients who had undergone excessive psychological stress. 2 cases were severe enough to require lateral tarsorraphy. 3 of the patients became worse while taking neomercazole. In benign cases the eye signs subsided with toxicity or did not progress appreciably.

TOXIC REACTIONS

No rashes, drug fevers, arthralgias, sore throats, or leucopenia occurred in any of the patients, and no other toxic manifestations have been seen to date. 3 of our patients had previously shown toxic reactions with methylthiouracil and 1 with 'Itrumil,' but had no ill effects from neomercazole.[‡]

Illustrative Case-records

TYPICAL RESPONSE IN AVERAGE CASE

Case 1.—A housewife, aged 32, was seen at the Royal Free Hospital in August, 1952, with five months' history of nervousness and irritability, insomnia, palpitations, and breathlessness on exertion. Loss of weight 11 lb. in five months.

On examination the thyroid showed firm generalised enlargement, estimated weight 40 g., with palpable thrill over both superior poles and intense systolic bruit over entire gland. Marked tremor. No eye signs. B.M.R. +34%. Pulse-rate 96, regular. Weight 115 lb. Serum-cholesterol 187 mg. per 100 ml. Maximum uptake of I^{131} 82% (normal 20–50%) at five hour (half-maximum in thirty minutes), declined to 78% at twenty-four hours. Thyroid/plasma clearance-rate 330 ml. (normal 10–42 ml.). Urine excretion 7% in twenty-four hours (normal 30–60%).

Aug. 26: treatment with neomercazole, 20 mg. daily, started.

Sept. 18: B.M.R. +10%; pulse-rate 80; weight 118 lb.; no thrill, bruit less loud.

Oct. 17: B.M.R. −10%; pulse-rate 78; weight 126 lb.; thyroid softer, bruit practically gone. Neomercazole reduced to 5 mg. a day.

Nov. 20: B.M.R.=0; pulse-rate 82; weight 128 lb.: thyroid now quite soft, no bruit. Neomercazole reduced to 4 mg. a day.

Dec. 30: B.M.R. not estimated; pulse-rate 76; weight 133 lb.; goitre soft, about 35–40 g., no bruit. Feels perfectly well on neomercazole 4 mg. daily.

RAPID RESPONSE

Case 2.—A housewife, aged 30, was first seen at the Royal Free Hospital in January, 1953, with four months' history of ravenous appetite, intolerance of heat, and severe nervousness, two months' history of swelling of neck, and five weeks' history of prominent eyes. No family goitre and no precipitating causes.

On examination she was severely toxic, thin, shaky, and breathless, with staring and restlessness. The thyroid showed firm generalised enlargement, estimated weight 70–80 g.; neck circumference $14^1/_2$ in.; palpable thrill over right upper pole; loud systolic bruit over entire gland but loudest on the right. Exophthalmometer readings R 16, L 15. Slight supraorbital swelling; moderate lid retraction and lid lag; no ophthalmoplegia or chemosis. Warm moist skin; fine and coarse tremor of hands. Initial B.M.R. +66% and repeat B.M.R. +63%, pulse-rate 130, regular; weight $119^1/_2$ lb.; height $67^1/_4$ in.; blood-pressure 185/55 mm. Hg; serum-cholesterol 104 mg. per 100 ml., thymol turbidity 5 units, flocculation positive. I^{131} iodide trap test uptake blocked with neomercazole 30 mg.= 34% of the dose taken up at $1^1/_4$ hours, decline to 30% at $2^1/_2$ hours. Administration of 1 g. of potassium thiocyanate was followed by rapid loss of iodide to 12% of the administered dose.

Jan. 9: treatment with neomercazole 40 mg. a day started.

Jan. 30: patient said she felt a different woman. Had gained $4^1/_2$ lb.; B.M.R. +7%; pulse-rate 68; blood-pressure 130/80 mm. Hg. Neomercazole reduced to 25 mg. daily.

Feb. 20: B.M.R.=0; pulse-rate 72; weight $127^1/_2$ lb.; exophthalmometer readings R 17, L 16; neck circumference $14^1/_2$ in., goitre size unchanged, thrill still present with loud bruit; no tremor. Neomercazole reduced to 20 mg. daily.

SLOW RESPONSE

Case 3.—A married clerk, aged 38, was first seen at the Middlesex Hospital on Feb. 19, 1952. In October, 1951, there had been a rapid onset of intolerance to heat, with excessive sweating, severe breathlessness on exertion, and palpitations at night. *In December, 1951, swelling of neck first appeared.* Weight had been lost from 10 st. 7 lb. to 8 st. $5^1/_2$ lb. in the last five months in spite of good appetite. Generalised pruritus.

On examination the patient was restless and looked worried, with a slight stare. The thyroid showed considerable, uniform, and moderately firm enlargement; estimated weight 60 g. Neck circumference 14 in. Much pulsation of goitre, with thrill over both superior poles. Intense systolic bruit over entire gland. Skin moist and warm; fine tremor of hands. B.M.R.=+45%; pulse-rate 106; weight 117 lb.

Feb. 22, 1952: treatment with neomercazole 30 mg. daily, started.

After four weeks' treatment pruritus had disappeared, and all other symptoms improved. B.M.R.=+29%; pulse-rate 92; weight 123 lb.

After eight weeks' treatment B.M.R.=+20%; pulse-rate 88; weight 126 lb.; goitre smaller and softer, estimated weight 50 g., no thrill, soft bruit only.

After sixteen weeks' treatment B.M.R.=−3%; pulse-rate 76; weight 137 lb.

After twenty-four weeks' treatment neomercazole was reduced to 15 mg. daily.

September, 1952: B.M.R.=+18%, pulse-rate 80. Dosage not changed, because patient still felt well.

November, 1952: recurrence of symptoms. B.M.R.=+14%; pulse-rate 100; weight 132 lb.; skin moist; slight tremor; goitre size unchanged, but bruit loud again. The dosage of neomercazole was increased to 30 mg. again.

Three weeks later all the symptoms had been controlled.

Follow-up.—Patient now on neomercazole 20 mg. a day; neck circumference is $13^1/_2$ in., and bruit is still present. Feels well and works full time besides running own home.

This patient may well come to operation, for after a year's treatment it has been impossible to reduce the dosage of neomercazole to a small maintenance dose.

OVER-TREATMENT

Case 4.—An engineer, aged 40, was admitted to the Royal Free Hospital on Aug. 30, 1952, with three months' history of lack of energy, nervousness, and shakiness, increased sweating, and intolerance of heat. He had lost 1 st. weight in a year, and for the last month had had palpitations on exertion.

On examination he weighed 9 st. $10^1/_2$ lb. Sweating was profuse. The thyroid was easily palpable; estimated weight 30 g.; soft bruit over both lobes. Fine tremor. No eye signs. Pulse-rate 100. Blood-pressure 180/90 mm. Hg. B.M.R. +38%.

After ten days' rest and 'Sodium amytal,' B.M.R. +27%, I^{131} maximum uptake 76%, half-maximum reached at fifty minutes, thyroid/plasma clearance 280 ml. per minute, urine excretion 6% in twenty-four hours. Serum-cholesterol 166 mg. per 100 ml.

Treatment and progress.—After ten days' treatment with neomercazole 30 mg. daily the B.M.R. was +3% and pulse-rate 90, and the patient had gained $6^1/_2$ lb. The dosage of neomercazole was reduced to 15 mg. a day, on which dosage the patient was discharged.

From October, 1952, to January, 1953, the patient attended another clinic, continued to take neomercazole 15 mg. daily, but did not have his B.M.R. estimated. From November, 1952, onwards, he had pain in his shoulders and back, slowing down and excessive sleepiness, and increasing sensitivity to cold. His skin became dry. No constipation.

On Jan. 12, 1953, he was seen again at the Royal Free Hospital, when his B.M.R. was −30%, pulse-rate 80, weight 11 st. 4 lb., eyes puffy, and speech slow and slurred. Neomercazole therapy was stopped. A week later his B.M.R. was −23%, serum-cholesterol 184 mg. per 100 ml.; thyroid still small and soft (estimated weight 30 g.), and no bruit was heard.

[‡] The number of patients treated with neomercazole has since increased to 150, and still no toxic reactions have been seen.

Recent Advances in Pathology

6th ed. Editor: GEOFFREY HADFIELD, M.D., F.R.C.P., Sir William Collins professor of pathology, Royal College of Surgeons of England. London: J. & A. Churchill. 1953. Pp. 367. 30s.

THIS well-known work can no longer be called Hadfield and Garrod, because it is now written by nine contributors under the general editorship of Professor Hadfield, while Professor Garrod, owing to increasing commitments has retired after sixteen years of collaboration. The large body of new knowledge which has accumulated since the last edition appeared six years ago is set out, mostly in clear and readable reviews.

In some chapters, notably those on liver diseases and pneumoconiosis, a little judicious cutting of older work, which tends to conflict with modern knowledge, would have given greater clarity; but on the whole this book presents clearly and concisely most of the advances of recent years. It is unfortunately inevitable that a survey of this kind is partially out of date before it appears, and we can only regret that it is not produced more often and the time taken in publication reduced; but the postgraduate student preparing for higher examinations and the busy practising consultant who wishes to get abreast of modern advances in specialties other than his own will find that it adequately fills the gaps in their reading.

Advances in Carbohydrate Chemistry

Vol. 7. Editors: CLAUDE S. HUDSON, National Institute of Health, Bethesda, Maryland; MELVILLE L. WOLFROM, department of chemistry, Ohio State University, Columbus; SIDNEY M. CANTOR, American Sugar Refining Co., Philadelphia. New York: Academic Press. London: Academic Books. 1952. Pp. 370. 60s.

THIS is a book for the research-worker specialising in the chemistry of carbohydrates and will probably be of little value to the general reader or even to many biochemists. For those actively engaged in this field however, it provides critical reviews on the chemistry of various carbohydrates and their derivatives written by experts. The high standard of the reviews published in earlier annual volumes of the series has been fully maintained in this. Of the eight reviews those dealing with derivatives of fucose, with fructose and its derivatives with 2-amino sugars, and with the size and shape of polysaccharide molecules have the most interest in medicine, but all are essentially chemical in viewpoint. Information about the molecular weights of various polysaccharides, including glycogen, bacterial dextrans, inulin, bacterial polysaccharides, chondroitin sulphate, blood-group polysaccharides, heparin, and hyaluronic acid, is summarised. The book is illustrated with numerous structural formulæ, and contains tables of chemical properties of carbohydrates and their derivatives.

The Stranger's Son

JOHN J. KEEVIL. London: Bles. 1953. Pp. 230. 21s.

THIS biography of Baldwin Hamey the younger, a leading physician of seventeenth-century London and the most liberal of all the benefactors of the Royal College of Physicians, is a sequel to the same author's *Hamey the Stranger*,[1] but is complete in itself. It is based on unusually intimate and previously unexamined manuscripts, mostly written in Latin, which give a detailed account of his youth and medical education at Leiden, Oxford, and London.

Through them can be seen his rise to eminence as a physician and his great influence over the college though he refused an invitation to be its president. Hamey successfully steered his way through the divided loyalties of Cromwellian England while secretly forming a collection of Stuart relics now at Windsor Castle. He lived to experience the plague in London and to witness the great fire from his new home in the country at Chelsea. A classical scholar he could read and write Latin prose and verse with fluent ease and when occasion demanded with wit. When the college building at Amen Corner near St. Paul's was subject to confiscation in 1651 Hamey redeemed the property out of his own private purse and preserved it for the college. He contributed liberally to the rebuilding fund after the fire. In addition he presented the wainscoting of fine Spanish oak which now adorns the censors' room, and made over to the college an estate in Essex to double the premium of the Harveian orator. He had no children, a good inheritance, and a lucrative practice. He was always well off and used his wealth with generosity all his life. He made gifts to London's churches, to Charles II and on several occasions he paid for the education of boys whose scholarship seemed deserving of help.

Dr. Keevil has assembled his facts into a readable and entertaining story and he gives a vivid picture of life in London at the time and of the administration of the college. The translation of medieval Latin must have been a big labour and is a work of scholarship and distinction.

Die Sprache des Menschlichen Antlitzes

4th ed. FRITZ LANGE. Munich: J. F. Lehmann. 1952. Pp. 237. D.M. 20.50.

WE all have to work out for ourselves a rough and ready gallery of correspondence between face and character, and we all suffer from the lack of an assured system. There have been many failures to reinstate Lavater or improve on him, but efforts to find a sound basis for this necessary art continue. Professor Lange, an orthopædic surgeon, has pursued the study of faces throughout his long life, in the belief that only anatomical analysis of expression and structure can provide the essential data for reading character. Consequently his book is rich in descriptions, which are precise about muscles and movements but woefully loose about traits of personality. Many of Dr. Lange's illustrations are of historical personages about whose character we know little, so he has had to rely on anecdotes and scanty or biased accounts. Some of his notions are very old fashioned: thus he suggests that much intellectual activity may make the brain grow more, thus bringing about in a young man the broad and high forehead of the thinker. The book contains much information much uncritical guesswork, and a pleasant seasoning of prejudices.

Traitement de la tuberculose par l'acide para-amino salicylique P.A.S.

Editors: JEAN PARAF, médecin de l'Hôpital Bichat, JEAN FOUQUET, Médecin de la Salpêtrière (Service des enfants). Paris: Masson. 1952. Pp. 404. Fr. 3200.

para-Aminosalicylic acid is considerably less effective than streptomycin and, though it is a valuable adjunct through its partial inhibition of resistance to streptomycin when the two are given together, its use alone has not been very popular in this country; indeed many consider that it should not be used by itself at all. But numerous patients have undoubtedly been treated with P.A.S., and the paucity of reports in the English journals suggests that the results have not been satisfactory. Much more attention has been given to it in France, and this book assembles the experience gained there. The section dealing with chemistry, pharmacology, and laboratory studies is useful and adequately documented, but the clinical section is too uncritical in the presentation both of reports from published work and of the authors' own observations. It is unlikely that the results described with oral or intravenous P.A.S. will change the present judgment in this country of the rôle of the drug in tuberculosis.

Polyglot Medical Questionnaire (London: H. K. Lewis. 1953. Pp. 62. 12s. 6d.)—Ten years ago[1] Dr. Chalmers Parry drew our attention to his polyglot medical questionnaire in 27 languages, then awaiting publication. Now, at long last, 12 of his 27 languages have been published and it is a pity that all 27 are not here. To communicate with a patient the questioner finds the required phrase numerically keyed in his own tongue, and points out to the patient the same number in the foreign tongue concerned. This method of communication does away with difficulties of pronunciation and phonetic spelling and unintelligibility of the patient's reply which is nearly always "yes" or "no". This questionnaire is limited to English, German, Dutch, Norwegian, Swedish, Danish, French, Spanish, Italian, Portuguese, Russian, and Polish.

Summary

A report is presented on the use of 2-carbethoxy-1-methylglyoxaline ('Neo Mercazole') a new anti-thyroid drug related to methimazole.

120 thyrotoxic patients treated with neomercazole were followed for periods up to twenty-one months. Of these, 30 patients received neomercazole preoperatively and 90 as curative treatment.

The optimum initial dosages were 15, 30, and 45 mg. a day for mild, average, and severe cases respectively.

Of the 120 patients, 93 became euthyroid within two to eight weeks, and 27 responded more slowly. Of the latter, 9 were operated on and the rest were controlled in three to six months.

Goitrogenic reactions were avoided, in all except 7 patients, by careful control of the maintenance dose.

No toxic reactions were seen.

The results are compared with those obtained with methimazole by other workers. Weight for weight, neomercazole seems to be at least as effective as, and very much less toxic than, methimazole.

I am grateful for constant encouragement and guidance to Miss G. Barry, senior surgeon at the Royal Free Hospital, under whose direction this work was done and who initiated the clinical trial in April, 1951, and operated on 30 patients. I am indebted to Sir Daniel Davies, Dr. P. E. Thompson Hancock, and Dr. Frances Gardner, physicians to the Royal Free Hospital, for allowing me to cite 15 cases treated by them. Dr. Gardner also supervised the cardiac aspect in our patients. Mr. R. Vaughan Hudson, senior surgeon at the Middlesex Hospital, gave me facilities to treat and to follow up 34 cases in his clinic: I wish to thank him for his keen interest and valuable help in this study. I also want to thank Mr. A. Lawson, PH.D., university reader in chemistry at the Royal Free Hospital, for his advice and help; and the physicists and the staff of the pathology departments in both hospitals for investigating our patients.

The drug used in this investigation was supplied by Glaxo Laboratories and by the British Schering Company.

"The closing sessions of the annual meeting of the American College of Physicians offered today a striking example of what a medical leader described as indifference by doctors to economic and social aspects of practicing medicine. Only fifty-three physicians among the 4,700 attending the week-long session went to hear Dr. Louis H. Bauer, president of the American Medical Association, and a panel of five medical authorities discuss how the public can pay for the excellent medical treatment that science now can provide. At the same moment, well over 1,000 crowded into another room of Convention Hall for an erudite clinical-pathological conference. Strictly scientific, the conference presented in detail two medical cases, at autopsy, which the average practicing physician would infrequently see in normal practice."—ROBERT K. PLUMB, *N.Y. THYROTOXICOSIS TREATED WITH 2-CARBETHOXYTHIO-1-METHYLGLYOXALINE

('NEO MERCAZOLE')

Sir HUGH POATE

M.V.O., M.B., Ch.M. Sydney, F.R.A.C.S., F.R.C.S.

HON. CONSULTING SURGEON, ROYAL PRINCE ALFRED HOSPITAL, SYDNEY

AFTER the first reports on the anti-thyroid activity of 'Neo Mercazole' (Lawson, Rimington, and Searle 1951, Lawson and Barry 1951), a small supply was sent to Sydney in May, 1952, for clinical trial.

PREAMBLE

With the advent of the "thio" compounds, introduced by E. B. Astwood, the treatment of thyrotoxicosis has undergone profound change. Medical treatment will now cure the majority of patients with early acute primary thyrotoxicosis—in my experience nearly 85%—while the remainder can be subjected to an operation of convenience. In the late stage of primary thyrotoxicosis, or in thyrotoxicosis secondary to an old colloid or adenomatous thyroid, the toxicity can be controlled in 2–3 months and the patient then treated by an operation which usually requires only 7–10 days in hospital, followed by rapid convalescence. Though the technical difficulty of operating on large glands is much the same as when iodine is administered to prepare the patient for operation, with adequate preparation there is no postoperative reaction to worry surgeons and nurses.

Of the various "thio" compounds, I finally selected methyl thiouracil as a standard means of treatment, with propyl thiouracil in reserve. However, a number of patients proved intolerant to both these compounds, and agranulocytosis kept occurring as wider use was made of this form of therapy by general practitioners. Hyperplasia of the thyroid has become common, because of overdosage and failure to give thyroideum siccum when control of toxocity has been obtained, while inadequate treatment, on the other hand, has resulted in many recurrences of thyrotoxicosis. What was wanted was a compound which would reduce the vascularity of the gland but would not interfere with the white blood-cells, induce hyperplasia of the thyroid, or cause perithyroiditis or reactions such as fever, rashes, or joint pains. Judging by experience up to date, neomercazole comes closer to meeting these requirements than any other compound yet introduced.

Compared with methyl thiouracil, neomercazole seems to have a more persistent effect on the thyroid and to cause greater regression of the hyperplasia with restoration of colloid storage. The glands of those operated on have shown relatively slight hyperplasia, and the longer the preparatory treatment the less the hyperplasia becomes. If confirmed, this observation will be important for long-term therapy; for in cases treated with methyl thiouracil recurrence takes place only in patients whose glands remain enlarged after adequate therapy: if the gland reverts to a normal size, there is no recurrence. Also it seems that neomercazole induces resolution of hyperplasia much more quickly than does methyl thiouracil.

THE CASES TREATED

Of the nine thyrotoxicosis cases I have treated with neomercazole, the first two were examples of acute primary thyrotoxicosis in which a good response to methyl thiouracil would have been expected. Having obtained good results I then tried the drug in cases where thiouracil had proved unsatisfactory or had produced side-effects. The usual dosage was 10 mg., three times daily until thyrotoxicosis was controlled, after

"I dread the rustling of the grass"

WILLIAM WORDSWORTH

No sooner has the blossom languished
and spring shed her coat of many
colours than the tall grasses ripen The air is
again pollen-laden To those who love the countryside
these richly-clothed meadows are a joy to
sufferers from hay-fever they are
merely the signal for a fresh period of acute discomfort
Yet there is a solution — BENADRYL,
probably one of the most potent of all histamine antagonists,
may be taken just before and during the
pollen seasons and, in the majority of cases,
provides effective relief

BENADRYL a successful anti-histamine

Capsules (25 or 50 mg.) in bottles of 50 & 500,
Elixir in bottles of 4 & 16 fl. ozs.

PARKE, DAVIS & Company, Limited [illegible] Hounslow, Middlesex Telephone Hounslow 2361 think that, once control of a primary thyrotoxicosis is obtained, a comparatively short period of maintenance therapy will bring about complete cure.

PRINCIPAL PHYSICIST, SHEFFIELD NATIONAL CENTRE FOR RADIOTHERAPY

THE first account of 2-carbethoxythio-1-methyl-lyoxaline (C.G.1) was published by Lawson, Rimington, nd Searle in 1951, and Lawson and Barry (1951) have eported on its clinical use in thyrotoxicosis.

Lawson et al. (1951) included in their report an account f the effect of C.G.1 on the metabolism of iodine as easured with the isotope I^{131}, and they showed that s effect was very similar to that of 1-methyl-2-mercapto-midazole, but the inhibitory effect on the uptake of iodine y the thyroid gland appeared to be more prolonged.

FFECTS OF 1-METHYL-2-MERCAPTO-IMIDAZOLE AND C.G.1 ON THYROID UPTAKE

ase o.	Drug	Dose (mg.)	Effect
1	1-methyl-2-mercapto-imidazole	10·0	Uptake completely inhibited
2	,,	2·5	Uptake completely inhibited (fig. 3)
3	,,	1·0	No effect
4	,,	1·0	No effect (fig. 4)
5	,,	0·5	Very transient partial suppression of uptake
6	2-carbethoxythio-1-methylglyoxaline	10·0	Uptake completely inhibited
7	,,	10·0	Uptake completely inhibited
8	,,	2·5	Uptake completely inhibited (fig. 1)
9	,,	1·0	Partial suppression of uptake
10	,,	1·0	Partial suppression of uptake
11	,,	0·5	Slight partial suppression of uptake
12	,,	0·5	Slight partial suppression of uptake (fig. 2)

We have assayed C.G.1 ('Neo Mercazole,' British chering) by the standard technique of Stanley and stwood (1947), so that its potency might be readily ompared with that of the numerous other compounds imilarly assayed. The technique has previously been pplied by Goodwin, Miller, and Wayne (1949) to other ubstances.

METHOD

After the administration of a tracer dose of radioctive iodine, a dose of an anti-thyroid drug is given to a atient. This changes the normal curve of accumulaion of iodine in the thyroid gland. In a normal person, f the activity of the thyroid is plotted against the quare root of the time, the curve persists as a straight ine for about ten hours, and any deviation from the ine is easily detected. Within limits, the extent of the eflection from the straight line can be related to he potency of the drug and the size of the dose.

The inhibitory effect of 1-methyl-2-mercapto-imidazole ras studied by Stanley and Astwood (1949), and we have ompared the action of this drug with that of C.G.1.

RESULTS

Graded doses of both drugs were administered to patients with normal thyroid function (see table) and typical results are illustrated in figs. 1–4.

In doses of 10 mg. both drugs caused complete inhibition of uptake of radioactive iodine by the thyroid gland during the whole period of observation, and a similar effect was observed with doses of 2·5 mg. of each drug (figs. 1 and 3). The effect is comparable to that of 200–300 mg. of methyl thiouracil.

At the 1 mg. dose level C.G.1 caused a definite but smaller depression of the curve, and even in a dose of 0·5 mg. the shape of the curve was consistently affected (fig. 2). With 1-methyl-2-mercapto-imidazole, however, no effect was noted in either of two patients to whom 1 mg. doses were given (fig. 4); and, except for one patient in whom a very transient inhibition of uptake was observed after a dose of 0·5 mg., we did not notice any effect in any patient with doses of this order.

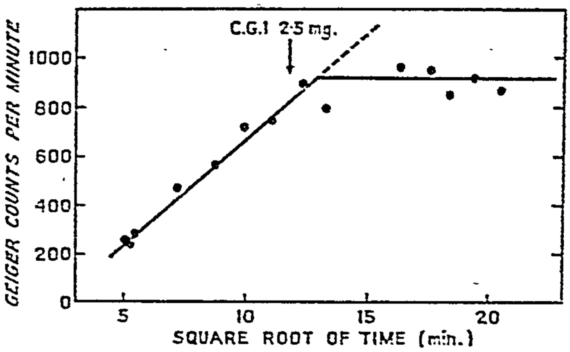

Fig. 1—Effect of 2·5 mg. of C.G.1 on accumulation gradient in thyroid gland.

DISCUSSION

Stanley and Astwood (1949) reported a definitely demonstrable effect with doses as low as 0·5 mg. of 1-methyl-2-mercapto-imidazole, but this was not invariable in our experiments. On the other hand, the anti-thyroid potency of C.G.1 is certainly as great as that of the other compound; and it may well be greater, for more consistent inhibition was obtained with single doses of it at levels of 1 mg. or less.

Further, the possible positive effect obtained in one patient with 1-methyl-2-mercapto-imidazole in dosage

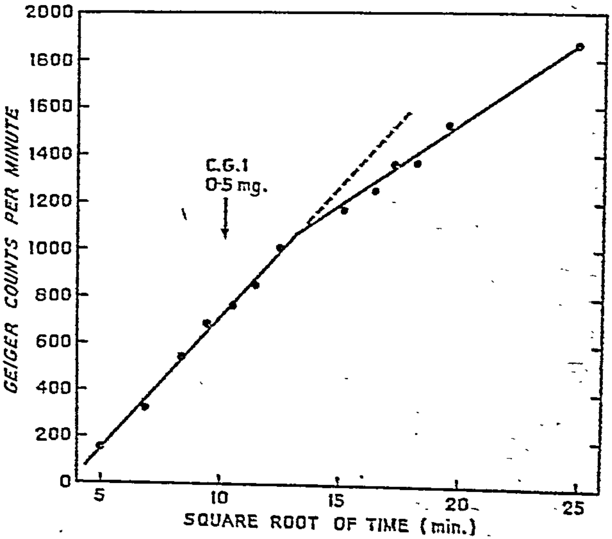

Fig. 2—Effect of 0·5 mg. of C.G.1 on accumulation gradient in thyroid gland.

contamination with carcinogens cannot be entirely excluded in any surroundings where they have been used, so readily do they become dispersed. Mere contamination was, however, an unlikely explanation of the malignant change in untreated cultures, for precautions were taken to avoid it, and FIROR and GEY[3] found, by chance, a similar transformation in the course of experiments requiring continuous culture of rat mesenchyme. This occurred in a laboratory into which no chemical carcinogen had knowingly been introduced. These workers also noticed altered appearances which led them to suspect malignant conversion. On inoculation into rats malignant tumours developed. In this case stray gamma radiation due to storage in the laboratory, at the time of early cultivations, of 50 mg. of well-shielded radium had to be considered as the effective cause of the change. On measuring the radiation in the region of the roller-tube drum about $^1/_{20}$ rontgen per day was detected; this applied to two out of three instances of malignant change but not to the third and possibly more.

Yet another example of malignant change in vitro, associated this time neither with chance nor with known carcinogen but with a deliberate attempt by other means, has now been reported by GOLDBLATT and CAMERON[4] in two cultures derived from 5-day-old rat heart. The means used to effect the change were intermittent deprivation of air and the substitution of nitrogen during prolonged propagation. Work was begun by GOLDBLATT in 1930 on a theoretical basis derived from WARBURG's studies of metabolism of various normal and malignant tissues in vitro. This work was abandoned and could not again be resumed until 1949, when GOLDBLATT and CAMERON started to test the idea that because surviving or temporarily growing tumour cells characteristically use the glycolytic mechanism as a source of energy, the enforcement of this mechanism on growing normal cells might impose the malignant conversion. It now appears that intermittent exposure to anaerobic conditions, with replacement of air by nitrogen in the culture-tubes, has twice, short of killing the cells, brought about, or been attended by, eventual malignant change. Five cultures of myocardium so treated died or were discarded on account of poor growth. A sixth culture was divided, and from it three substrains were grown. One line of cells was propagated in the usual way and never exposed to nitrogen. It eventually developed into a strain of pure fibroblasts which served as controls throughout the experiments. Its progeny underwent no further unusual morphological variation and did not give rise to tumours on inoculation into rats; the other two strains were deprived of air and exposed to nitrogen intermittently, the second being derived from the control subculture one year later than the first. The cells of both developed striking morphological alterations in about a year and after several unsuccessful attempts, gave rise on inoculation, using a special device, to serially transplantable fibrosarcomas. The special device, due to a technique used by H. S. N. GREENE, was the inclusion with the test inoculum of a small fragment of embryo rat lung from the same rat strain. Subcutaneous nodules then became visible and palpable in 3 or 4 days and grew progressively and in serial transplants.

GOLDBLATT and CAMERON suggest, but do not claim to have proved, a causal relationship between intermittent anaerobiosis and malignant conversion. They recognise the difficulty of reconciling their findings after deliberate intervention with the apparently spontaneous transformations of EARLE and of GEY and his associates. They think that in fact GEY's cultures may often have been exposed inadvertently to oxygen lack under the experimental conditions used. Some morphological and biological observations by LUDFORD and BARLOW[5] on cultures of mammary carcinomas of mice under ordinary conditions must also be taken into account. These observations suggested—though they never finally proved—that accompanying connective tissue cells had undergone sarcomatous transformation. Only further work undertaken to test whether results are repeatable sufficiently often to be relied on and duly controlled will settle the relation of anaerobiosis to malignant conversion. As in the natural history of malignant disease, time again appears to play a ruling part. Perhaps epithelium and cells from animals other than rats will now be tested by the same methods. Malignant change is notoriously easily induced in rat connective tissues, but this does not detract from the value of these stimulating experiments.

Puerperal Mastitis

UNTIL recently interest in the painful condition of puerperal mastitis was directed more towards treatment than towards prevention. Typically mastitis and breast abscess develops rather late in the puerperium—most commonly in the third and fourth weeks. Thus obstetricians and midwives, whether they work in or outside hospital, do not see nearly all the instances of this complication; it is the surgeon and the pædiatrician who are continually reminded of it.

Careful observation has shown that mastitis is closely associated with early breast engorgement and feeding difficulties due to abraded or cracked nipples. Where lactation starts by sudden engorgement, the nipples become œdematous and thus especially liable to damage. This liability is further increased because the baby, unable to get the areola in his mouth, munches the nipple; and once damaged the nipple is open to infection. Only about 30% of women are so fortunately fashioned that their nipples protract well and there is no obstruction to the outflow of breast secretion in the later months of pregnancy, or of milk after delivery. In such cases the baby takes the nipple well into his mouth; his gums are applied to the areola, and milk squirts almost effortlessly down his throat; there is little or no engorgement; and there is a minimum of friction of, or of danger of damage to, the delicate epithelium of the nipple since no force is applied to it. The majority of women, however, need help and instruction, not only to remedy nipple defects antenatally, but also so that they may learn in good time how to express secretion in the later months of pregnancy and clear the way for the free flow of milk after delivery. Anatomical

CASE-RECORD

A man, aged 63, was referred to us by Mr. H. S. Gild because of recurrent epistaxis. In 1946, when he had his first attack, he consulted another otolaryngologist, who cauterised his nose without benefit. In 1947 he was admitted to another hospital with severe anæmia. On the basis of a high colour-index, pernicious anæmia was diagnosed and the patient was transfused with a pint of whole blood, after which he had an intermission of five months before his symptoms returned. He had then, on the average, an attack every 7–10 days. He was admitted to Farnborough Hospital on Nov. 10, 1949. His family history contained nothing significant. He admitted taking four or five pints of beer a day since the age of 20.

On admission physical examination showed no abnormality, apart from some dilated venules on the nose. The liver was not enlarged, and the reflexes were normal. Examination of his blood showed red cells 2,900,000 per c.mm., Hb 7·85 g. per 100 ml., white cells 4700 per c.mm., erythrocyte-sedimentation rate (E.S.R.) 148 mm. at 1 hour (Westergren), bleeding-time 2 min. 30 sec. (Dukes), clotting-time 3 min. (Lee and White), prothrombin 100%. Of liver-function tests; the thymol turbidity and thymol flocculation tests were negative, and the Kunkel test showed 1·5 units. A sternal-marrow count showed no evidence of pernicious anæmia.

Treatment and Progress.—The patient was treated with iron, his anæmia improved, and he was discharged.

On readmission on Nov. 22, 1950, with a history of epistaxis during the past year, his liver was not enlarged and his tendon-reflexes were all present. Blood examination showed red cells 2,700,000 per c.mm., Hb 8·39 g. per 100 ml., white cells 5700 per c.mm., E.S.R. 155 mm. at 1 hour (Westergren); bleeding-time 19 min., clotting-time 9 min., prothrombin 100%, calcium 10 mg. per 100 ml., uric acid 0·9 mg. per 100 ml. Liver-function tests: serum colloidal gold nil, thymol turbidity +1, thymol flocculation nil, Kunkel 1 unit, Popper 30 units. Galactose tolerance was normal, and the urea-clearance 125%. The serum gave a very strong formol-gel reaction without turbidity. Radiographs of all the bones were normal.

After discharge the patient attended as an outpatient. His Hb never increased above 9·29 g. per 100 ml., nor his red cells above 2,900,000 per c.mm. The anæmia was normocytic throughout. The E.S.R. was 140–155 mm. at 1 hour (Westergren). Wassermann and Kahn tests were negative.

On readmission on Aug. 6, 1952, he had a sallow complexion, with dilated veins and a nævus on his nose; there were also dilated veins on the face and at the thoraco-abdominal junction. His liver was palpable 4 in. below the costal margin in the right midclavicular line; it was firm, regular, and not tender. There were a few firm enlarged glands in both groins. The pupils reacted normally to light and on accommodation. Reflexes in the upper limbs were normal, and the abdominal reflexes were brisk. The knee-jerks could be obtained with reinforcement, the ankle-jerks were absent, and there was a normal plantar response. Sensation was everywhere normal, and the tendo Achillis on each side was sensitive to pressure.

Blood Examination.—Very great difficulty was met with in making any pathological examination, because his blood set almost immediately into a solid gel. However, by taking blood with a warm syringe and doing all the tests at 37°C it was possible to obtain the following results: red cells 2,000,000 per c.mm., Hb 7·8 g. per 100 ml., bleeding-time 8 min., clotting-time 8 min. 30 sec., prothrombin 100%, calcium 10·8 mg. per 100 ml., blood-urea 25 mg. per 100 ml., uric acid 6·4 mg. per 100 ml. (normal 2–4 mg. per 100 ml.), and cholesterol 65 mg. per 100 ml. (normal 140–310 mg. per 100 ml.). Liver-function tests: serum-colloidal gold nil, thymol turbidity +1, thymol flocculation nil, Kunkel 1 unit, Popper 37 units. Urea-clearance and bromsulphalein tests were normal. Biopsy of sternal marrow showed a normocytic picture.

Diagnosis.—Chronic alcoholism with cirrhosis of the liver was diagnosed, the anæmia being due to a combination of these factors and the frequent epistaxes.

SERUM-PROTEINS

In this patient the serum-proteins were estimated on three occasions, with the following results:

	Nov. 24, 1950	*Jan. 18, 1951*	*Feb. 20, 1951*
Total protein	5·4	7·8	8·45
Albumin	1·4	2·5	2·90
Globulin	4·0	5·3	5·55
A/G ratio	1 : 2·2	1 : 2·1	1 : 1·93

On readmission on Aug. 6, 1952, electrophoresis of the serum-plasma and urine (Griffiths 1952, 1953) showed the presence of an abnormal fraction situated between the β and γ fractions but distinct from fibrinogen, the result being:

Total protein	11·70 g.	Fibrinogen	1·10
Albumin	2·77	Cryoglobulin	6·15
α_1-Globulin ..	0·44	γ-Globulin	0·32
α_2-Globulin ..	0·33		
β-Globulin	0·59		

The addition of 0·1 *N* NaOH to the serum produced an immediate solid gel of the consistence of india rubber; this was slowly reversible on neutralisation. Two-dimensional electrophoresis (Kunkel and Tiselius 1951) showed the homogenicity of the abnormal fraction and suggested that the albumin consisted of two components of slightly different mobilities. The urine contained a trace of protein; 200 ml. of this was dialysed against 50% dextran to dryness and resuspended in 0·5 ml. of saline solution and run electrophoretically. This protein had the same mobility as the abnormal fraction in the blood.

Prolonged centrifuging of serum or of plasma in the cold failed to separate the cryoglobulin. Hill et al. (1949) reported in their case similar negative results after blood-transfusion, and no doubt the blood received prevented the development of this phenomenon.

In one experiment in the present case the proteins were precipitated by the method of Popper and the centrifuged deposit was dialysed against water and resuspended in physiological saline solution. This fraction on electrophoresis consisted entirely of the abnormal protein, but the reconstituted serum did not exhibit the cold precipitation of cryoglobulin. It therefore seems that reversible cold precipitation is not an inherent property of this type of protein but depends on some other factor not yet identified. de la Huerga et al. (1950) showed that the Popper method is almost specific for γ-globulin; this is true for serum, but we have found that fibrinogen is also precipitated by this method, and the results obtained are due to the close relation between the cryoglobulin and true fibrinogen.

Judging by the Popper reaction of 30 units in 1950 the blood in the present case was already beginning to form the abnormal protein, but it was not until a year later that its presence was manifested by the difficulty encountered in performing the usual blood examinations.

McFarlane and Dovey (1952) have described a case very similar to ours. This was in a younger man, aged 42, who also presented with epistaxis. The abnormal protein migrated between the β and γ peaks. In this case abnormal plasma cells appeared in sternal-marrow biopsies in the later stages and were found in the abdominal lymph-glands and liver after death. In view of these findings we have re-examined the marrow smears taken in 1949 and 1952 and can find no evidence of abnormal cells. As the patient has also an enlarged liver and a few enlarged lymph-glands, we cannot say that he will not eventually have multiple myelomata. At the time of writing he is comparatively fit and we have no evidence that our clinical diagnosis is incorrect, but the possibility remains.

SUMMARY

Cryoglobulinæmia developed in a patient with chronic alcoholism.

Experiments are described in which an attempt was made to identify the abnormal protein.

The reasons why this is regarded as an abnormal fibrinogen fraction are given.

Our thanks are due to Miss V. Anne Brews, our senior biochemical technician, for her aid in this investigation.

References overleaf

from infections to cancer[14,15] and might be extended still further Doctors who are interested will find guidance on methods of making and using maps for different purposes in a book[16] by two members of the department of geography in the University of Liverpool Doctors as well as the "historians, economists and ethnologists" for whom the publishers recommend the book will profit from instructions about the technique of drawing maps and from examples of the use of maps to portray an area's physical characters, and its climate, economics, population, and settlement The book will also assist in the choice of suitable diagrams to convey the facts elicited from statistical tables—a choice made expertly by Cohn and Lingg[17] Modern cartography can, like modern meteorology, bring help to medicine, and the results of cross fertilisation between the sciences may be both fascinating and useful

OBSERVATION AND INTERPRETATION

In the radiological assessment of pulmonary tuberculosis it is fairly easy to define the extent of the disease, but its character is much harder to estimate with accuracy The radiologist first describes shadows in the lung that is an observation If he then calls them "primary," "post-primary," "recrudescent," "exudative," or "fibrotic," he makes a deduction from the observation And at present deduction from radiographic to pathological appearances is by no means exact Sometimes it is pure guesswork, and sometimes it is based on reasonable probabilities There are therefore two main sources of error in radiological interpretation errors due to observation and errors due to deduction The latter are the commonest, and, therefore, the extent of the disease is more accurately recorded than its type

Several analyses of observer error in the *interpretation* of chest radiographs have been made in America in the past few years[18-20] And in this country Cochrane and Garland[21] found that among British radiologists the error was much less when the appearances were classified as "inactive" or "clinically significant," including two subgroups, "active" and "inactive, but clinically significant," instead of simply "inactive" or "active" There are those who regret the lack of any generally acceptable and workable classification based on pathological changes, but there are serious difficulties in the way of making and using such a classification The interpretation of a particular shadow or set of shadows in terms of morbid anatomy is often a matter of dispute Moreover, different people use identical terms for different things—"fibrosis" and "infiltration" are examples Last year a committee formed by the Joint Tuberculosis Council, the Faculty of Radiologists, and the Society of Thoracic Surgeons published a valuable report[22] which aimed at overcoming the difficulty of terminology The general adoption of its recommendations would certainly make radiological deductions more precise and helpful

A recent article by Edwards et al[23] illustrates some of these difficulties Over 4000 Americans rejected for military service on the ground of abnormal chest radiographs were re examined after an interval of approximately two years, and the lesions were classified as "stationary," "regressive" or "progressive" The object of the study was "to determine whether it was possible to separate certain types of minimal lesions according to their relative risk of progression on the basis of their roentgenographic appearance" The classification of the American National Tuberculosis Association was used, and the films were read by two observers independently It was originally intended to analyse progression-rates by pooling the two readings, but, because of the difference in interpretation, separate analyses had to be made—which illustrates the importance of the subjective factor in applying the N T A classification There was reasonably close agreement on the extent of the lesion, but "the two interpreters appear to have somewhat different patterns of classification for type of lesion" While Dr A said that 34 9% of the initial films of people under 25 showed "exudative" or "exudative productive" lesions and 46 1% showed "productive" and "fibro-productive" lesions, the corresponding figures for Dr B were 24% and 57 7% Moreover, Dr A found "exudative" and "exudative-productive" lesions to be twice as common among non-whites as whites, while Dr B interpreted both groups of patients as showing the same relative frequency Subjective variations in individual radiological interpretation cannot, of course, be eliminated, but these differences suggest that this particular classification is unsatisfactory It is an attractive step—and a logical one—to classify the radiographic changes of pulmonary tuberculosis pathologically, but it will not really clarify a confused subject until the deductions can be made with more accuracy Meanwhile, the correlation of pathological findings in the many resected specimens now available, with previous radiographic appearances would be helpful

CRYOGLOBULINÆMIA

Serum, as every schoolboy knows, is the fluid expressed from the clot of shed blood Much serology, however, consists in the study of a very *different* fluid, often obtained from blood kept in a refrigerator for hours or days, centrifuged more or less vigorously (perhaps while still cold), and immersed in a hot water bath (hot enough for example, to kill many organisms) Most known antibodies appear to survive this onslaught and remain detectable by established techniques, but in looking for components in serum of possible significance in disease the serologist is handicapped if he confines his attention to such serum Cold precipitating globulin may be an instance This has been described mainly in conditions accompanied by hyperglobulinæmia (e g, multiple myeloma, kala-azar, malaria) and interest has centred chiefly on the associated Raynaud like symptoms which have been attributed to the peculiar physical property of cryoglobulins

These proteins commonly precipitate on standing in the cold (4°–11°C) and redissolve on warming Electrophoretically, they apparently resemble gamma globulin,[1,2] but in this issue Dr Griffiths and Dr Gilchrist report a case where the abnormal protein fraction in the blood seemed to be more closely related electrophoretically to the fibrinogen fraction Concentrations found in the blood vary over a wide range Barr et al[1] describe a case of multiple myeloma where routine laboratory investigation of serum showed a total protein level of 7 7 g per 100 ml, with globulin 2 6 g per 100 ml The grossly abnormal, jelly like nature of the blood on withdrawal led to re estimation of protein on a sample kept at body temperature until clot retraction was complete, total protein was then found to amount to 15 g per 100 ml, with 11 g of globulin, 8 9 g of which was cold precipitable It is clear, then, that cryoglobulinæmia especially when mild is easily missed

the leg that had followed a period of failure in the adequate control of fibrillation four months after operation, although the size of the valve opening had been greatly increased.

No patients were included who were thought to have active rheumatic carditis, aortic valvular disease, or mitral regurgitation as the main lesion. Good results were not prevented by some degree of aortic disease, mitral regurgitation, calcification of the mitral valve, thrombosis in the left auricle, or functional tricuspid regurgitation. The whole valve mechanism might be so fibrosed and deformed that improvement in its function was impossible until the surgeon could be given more time and freedom by some form of artificial heart. The combination of mitral regurgitation, gross calcification, and a large heart made success unlikely, because the valve was almost certainly beyond help. The best indication of free mitral regurgitation was a loud systolic murmur heard at the apex and well conducted. Expansile pulsation of the left atrium seen in the anteroposterior view on radioscopy was confirmatory evidence; but some mistakes were still difficult to avoid, and so far catheterisation had not helped.

Considerable pulmonary hypertension with systolic pressure above 100 mm. Hg did not prevent excellent results, and the pressure in the pulmonary artery might fall to half its previous value or less. Most of the excellent and good results were in patients who had had pressures in the pulmonary artery of 60/35 mm. Hg or more. There had, however, been a few good results where the pressure at rest was hardly raised; probably in these cases the pressure rose unduly on even the slightest exertion, with little or no increase in the cardiac output. Pulmonary hypertension was, therefore, often an indication for operation; but generally the decision could be taken on clinical evidence alone.

Mitral valvotomy should be considered in all patients with mitral stenosis who were progressively disabled. Orthopnœa, cardiac asthma, pulmonary hypertension, and recurrent pulmonary œdema were special indications. Active rheumatic carditis, gross mitral regurgitation, and right-sided congestive heart-failure that could not be relieved were the main contra-indications.

So far there was no evidence that the good results were not lasting, but patients had been observed for only from two to four years.

Reviews of Books

The Neurophysiological Basis of Mind

The Principles of Neurophysiology. JOHN CAREW ECCLES, F.R.S., professor of physiology, Australian National University, Canberra. Oxford: Clarendon Press. 1953. Pp. 314. 25*s.*

LAST year Professor Eccles delivered his eight Waynflete lectures to an audience which seemed to grow larger week by week. The lectures were delivered in the manner of brilliant extemporisations: this book is their closely reasoned and fully documented source. Its publication is an important landmark; for in it one of Sherrington's collaborators surveys the working-out of many conceptions which when first framed were less readily amenable to experimental testing than they are today.

The first two chapters review the Cambridge school's account of ionic relationships in excitable tissues. They might be taken from some future textbook of advanced physiology: they may not be read as substitutes for the original articles and reviews; their purpose is to state at the outset those properties of peripheral plasma membranes in terms of which central processes may be tentatively interpreted. The main interest lies in the middle four chapters, which deal with the themes of Eccles's own experimental work—peripheral and central junctional transmissions and the coördinating function of the spinal cord. Study of the physiological reactions of spinal motoneurones has been revolutionised by the intracellular microelectrode technique. This has furnished proof of the postsynaptic nature of excitatory and inhibitory effects, for it records the lowering and raising of membrane potential when the neurone is bombarded by excitatory and inhibitory synapses, as well as the reversal of membrane potential when an impulse is discharged. These are over-all potential changes across the cell-membrane. The microelectrode presumably penetrates the soma or larger dendrites, and local and propagated activity in the outlying dendritic forest still needs to be elucidated.

The foregoing analysis measures time on a millisecond scale. A specially interesting chapter presents new evidence that even the most elementary spinal reflexes may be more enduringly modified by repetitive stimulation, and suggests that similar long-duration reactions may be the basis of conditioning and learning. A theoretical chapter on the cerebral cortex attempts an interpretation of its known spontaneous and evoked electrical potentials in terms of spinal motoneurone properties and cortical histology. The last chapter, on the mind-brain problem, is frankly disappointing. Different readers will find it so for different reasons, and especially, perhaps, readers who agree that "for the scientist there should be no doubt that the problem of interaction of mind and matter is a real problem and not a pseudo-problem arising from confusions in the usage of words."

One of the most stimulating characteristics of the book is its highly articulated argument. The results of each step in the analysis are used to the full in the interpretation at each succeeding stage. Thus the ionic hypothesis is used in the interpretation of fundamental neurone properties: inhibition of a motoneurone, for example, is supposed to be due to the action of a specific chemical transmitter on the pumping of sodium ions outwards across its membrane. And neurone properties are used in their turn in the explanation of spinal reflex activity and cerebral activity. But the detailed nature of such explanations is not meant to imply that we already know all the neurophysiology we need to know. Professor Eccles has always used detailed and elaborate working hypotheses, and he has never hesitated to discard them—as for example in the cases of the Golgi-cell theory of inhibition and the electrical theory of synaptic and neuromuscular transmission—if later experiment has convinced him that they were wrong.

Textbook of Pædiatrics

Editors: G. FANCONI, M.D., professor of pædiatrics, University of Zürich; A. WALLGREN, M.D., professor of pædiatrics, University of Stockholm. Editor: W. R. F. COLLIS, M.D., F.R.C.P., lecturer in pædiatrics, University of Dublin. Translator and co-editor E. KAWERAU, M.B., M.SC. London: Heinemann Medical Books. 1952. Pp. 124. £7 7*s.*

THIS, the leading Continental textbook of pædiatrics, was conceived by two of the most famous European pædiatricians at the end of the late war. It is based mainly on the pædiatric centres of Switzerland and Sweden, of which Fanconi of Zürich and Wallgren of Stockholm are the respective leaders; but there are are also contributions from eminent pædiatricians in several other European countries. The work, first published in German in 1951, represents the contemporary outlook of pædiatricians on the Continent. For the more recent English edition it has been revised, and a new chapter on megacolon added by Dr. M. Bodian. Among other subjects its 23 chapters cover the sociological aspects of pædiatrics, heredity, the psychology of the normal and the abnormal child, diseases of the skin, diseases of the eyes, surgical conditions in childhood, and diseases of childhood peculiar to hot climates. The views expressed correspond closely, in general, with those in British and American pædiatric works, although in the chapter on disorders of nutrition in infancy, some will regret the tendency to perpetuate the hypothetical classification and outlook of Czerny and Finkelstein. The immense task of translation has been creditably accomplished, though occasional imperfections might have been eliminated by stricter editing.

spread by the biopsy. The full cooperation of the patient is essential, and it says much for the technique developed by Christian that not one of his patients refused a second biopsy when it was necessary.

A report[3] from the hepatitis centre for Japan and Korea illustrates particularly well the importance of liver biopsy in the work of such a unit. During nine months in 1950–51, 2351 patients were seen at the centre, and 84 biopsies were performed on 73 patients without a single untoward incident. In 35 cases the biopsy was required because the diagnosis was still in doubt, despite considerable clinical and laboratory inquiries. It is interesting that in only 13 of these was the diagnosis of infective hepatitis confirmed; in 12 liver disease other than hepatitis was discovered; and in the remaining 10 the liver was excluded as the cause of the patient's symptoms. In another 35 cases the biopsy was performed because the disease was particularly severe or lasted a long time. There was continued activity of the inflammatory process in 21 of these livers, postnecrotic scarring in 8, and fatty metamorphosis in the remaining 6. Despite the claims to the contrary,[4–6] *no correlation could be established in this series between any of the laboratory or clinical findings and the pathological changes in the liver.* In the 3 remaining patients biopsy was performed because the jaundice returned after apparently complete recovery. All 3 showed the histological picture of acute hepatitis, and complete recovery followed a further period of hospital treatment.

Liver biopsy is also a help in evaluating specific methods of treatment. In fatty infiltration, for example, the administration of lipotropic substances produces a progressive diminution of fat, which may readily be assessed by biopsy. With the greatly increased safety of needle biopsy, the value of many other methods of *treatment may be convincingly demonstrated in this way.*

HMCs ON NHS

LIKE the rest of us, the council of the Association of Hospital Management Committees do not believe that all is for the best in the best of all possible hospital services. But they think that much less is wrong than might have been expected considering its size and complexity. Furthermore much of what is wrong is due to national economic difficulties rather than to a change of administrative heart. "The policy of centralisation carried out over the past four years is not necessarily the result of original sin on the part of successive Ministers and their advisers . . . and may even have been opposed *to their desires*." The association deplore the ever stricter financial control which has been imposed, but they recognise that the service has achieved a good deal even in four fairly difficult years, and they feel that it would be *folly to scrap the present system* without giving it a chance to prove itself in easier conditions. In their realistic report[7] on the N.H.S. they have therefore contented *themselves* with suggesting amendments within the present administrative framework.

Most of the criticisms of the health service are directed to the relation of the various statutory bodies to each other and to the Ministry. "Increasing financial control has upset the delicate balance of the different bodies and the H.M.C.s *have* been brought more and *more* into a position of . . . direct administrative responsibility to the Ministry." But the association do not altogether welcome this rapprochement, for they fear that, if the R.H.B.s were not there, "the place would inevitably have to be filled by something else, which would presumably be the regional officers at the Ministry." They reiterate the familiar complaint that greater centralisation has led to delay, inefficiency, and frustration, but they prescribe an injection of independence and responsibility rather than administrative reorganisation.

The system of appointment to R.H.B.s and H.M.C.s is also often criticised. Some would like to claim the right for groups or interests to appoint their own representatives. But the association stoutly oppose *this suggestion* and indeed believe *that* the representation of special interests on hospital authorities has already *gone too far. Instead they ask for more effective* representations of the patient. This can best be achieved, they hold, by confiding to laymen the chief responsibility for administration. They show a praiseworthy detachment in their opposition to the suggestion that every *H.M.C. should* be represented on the appropriate R.H.B., and they declare that it would "be fatal if Regional Boards were to become the battleground for Hospital Management Committees in competition for the Board's limited resources." A person with wide experience of hospital work should be allowed to serve on both bodies, but he must remember that he is a member of the regional board because of his personal qualifications and not as spokesman of his own H.M.C. The association are also against the suggestion that local authorities should have a right to representation on hospital authorities. Not only would they regret the encroachment of party politics on the neutrality of the health service, but they think that many an excellent person would be lost to the hospital service if he had first to pass a local authority sieve. In opposing election from below, the association also support selection from above. They regard it as no more than reasonable that the Minister *who* is responsible for the working of the service should have a say in the choice of people who are helping him in this task, and in particular of the chairmen. They see no *evidence that the present system has produced* "a class of chairmen who are 'Yes Men' or that those who have been appointed have failed to secure the confidence of those over whom they preside."

TRANSILLUMINATION OF THE STOMACH

As a method of clinical examination, transillumination *has limited value, and commonly the information that* it yields is misleading. Celli[1] has applied transillumination to the stomach. First a gastroscope is introduced; then, with the patient in the left lateral position, the illuminating bulb of the gastroscopy is used as the source of light. The bulb is directed towards 11 o'clock from a position in the middle third of the body of the stomach. By premedication Celli aims to decrease stomach tone, make insufflation easier, and thus improve the transillumination. The contra-indications are those of gastroscopy, with the addition of gastric resection and a very thick abdominal wall, which cuts down the amount of light at the skin surface. The whole of the stomach may be outlined except part of the fundus, and even the first part of the duodenum may be seen. Peristaltic waves can be observed, and when there is rigidity of the curvatures the contraction shadows are not present and the rigid area remains illuminated continuously. Celli claims that it is possible to estimate gastric tone by this method, and even to recognise the position of the vascular network running along the curvatures of the stomach.

Celli's article is illustrated by coloured drawings of his observations. These are interesting, but perhaps few at present would care to substitute transillumination for the established *methods of investigation.*

THE next session of the General Medical Council will open on Tuesday, May 19, at 2 P.M., when Prof. DAVID CAMPBELL, the president, will deliver an address. The Medical Disciplinary Committee will meet on Wednesday, May 20, at 2 P.M.

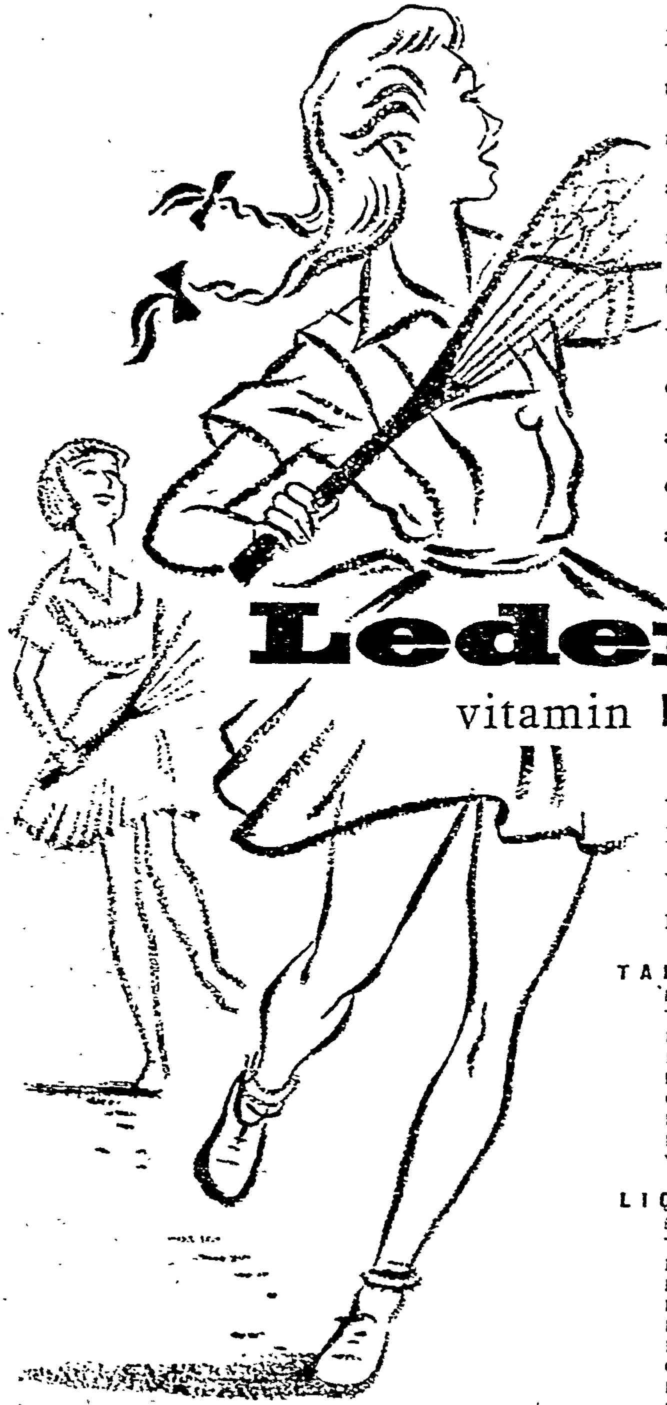
Good health for all . . .



If every child in the world could have the physical advantages of these children, many of the ills that plague juvenile and adult life would disappear. Good health and nutrition go hand-in-hand; but, unfortunately, *well-fed* does not always mean *well-nourished.* Where there is any deficiency of the factors of the B complex, as the result of malabsorption, deficiency in the diet, or other causes, an ideal supplement and therapeutic aid is . . .

Lederplex*

TRADE MARK

vitamin **B** complex *Lederle*

Administered in adequate dosage, daily, LEDERPLEX will supply all the deficient vitamins of the B complex which tend to promote normal cellular life and growth.

TABLETS

Each tablet contains:

Thiamine HCl (B_1)	2.0 mg.
Riboflavin (B_2)	2.0 mg.
Niacinamide	10.0 mg.
Pyridoxine HCl (B_6)	0.1 mg.
Calcium Pantothenate	3.0 mg.
FOLVITE Folic Acid	0.2 mg.
Insoluble Liver Fraction	250.0 mg
Vitamin B_{12}	1.0 microgram

LIQUID

Each teaspoonful (4 cc.) contains:

Thiamine HCl (B_1)	2.0 mg.
Riboflavin (B_2)	2.0 mg.
Niacinamide	10.0 mg.
FOLVITE Folic Acid	0.2 mg.
Pyridoxine HCl (B_6)	0.2 mg.
Pantothenic Acid	2.0 mg.
Choline	20.0 mg.
Inositol	10.0 mg.
Soluble Liver Fraction	470.0 mg.
Vitamin B_{12}	5.0 micrograms

Tablets: Bottles of 100 and 1,000
Liquid: Bottles of 4, 8 and 12 fl. oz.

didactic Generally speaking it was felt that the trained social worker should play a responsible part in administering services that sought to meet the needs of people Certainly he was required for carrying out such services, and where he undertook personal work it was the continuity of his rôle that was important breaks in human contacts impaired the chances of building constructive relationships with clients

There seemed to be unanimous recognition of the need to increase the use of general family case workers in the social services and to reduce the types and uses of specialist workers This recognition had obvious implications for training There should be a common basis of training for all types of social work and strengthening of the case-work training now provided Special attention should be paid to the needs of those already employed by means of in-service training, to refresher courses as a normal accompaniment to professional life, and to special courses for tutors and those with responsibility for supervising staff One group had suggested the need to set up a professional institute to set standards of training and to approve qualifications put forward

There was apparently cordial recognition of the part that can be played by volunteers, who were said to be increasingly ready to accept the idea of some measure of training The extent to which the health visitor with a radically revised training might fulfil a still wider rôle as the general family visitor was frequently referred to So, too, was the possibility of developing a local authority family welfare service, this was sympathetically discussed, particularly as it appeared to present the best hope of a coordinate and preventive service

Coordination of existing services, rather than more workers, was said to be the crying need Workers in the various services were still not sufficiently familiar with one another as individuals or with each other's methods and objectives One department of the local authority might act as a main inquiry centre for individual cases and see that these were appropriately referred The case conference method now used by most local authorities in connection with neglected children brought together administrative officers and field workers from their departments and from voluntary bodies This method came in for commendation and was thought to be applicable to individual cases of other types

Conclusion

This conference made many people think, and it is noteworthy that the thinking was on the whole objective Our social services have now reached a stage when some rationalisation and realignment is again due To the consumer confusion must be obvious, but the solution obscure It is to the credit of these assembled social practitioners that they tried to look afresh at the services in which they are engaged, to point out the problems and some possible solutions They and the community at large appear now to deserve some further help and guidance from those engaged in teaching and research and those who determine policy

COLLEGE OF GENERAL PRACTITIONERS

At the end of March, when the college was three months old, the number of foundation members was 1807 Their geographical distribution throughout the British Isles is shown on the accompanying map

It has been suggested that the regional faculties (whose names are printed in italics) should comprise the following areas.

ENGLAND

London —County of London

Home Counties South —Kent, Surrey, Sussex, Hampshire, and the Isle of Wight

Home Counties North —Middlesex, Essex, Hertfordshire, Bedfordshire

Oxford —Oxfordshire, Berkshire, Buckinghamshire

Cambridge — Norfolk, Suffolk

Bristol —Wil Dorset

Exeter —Dev

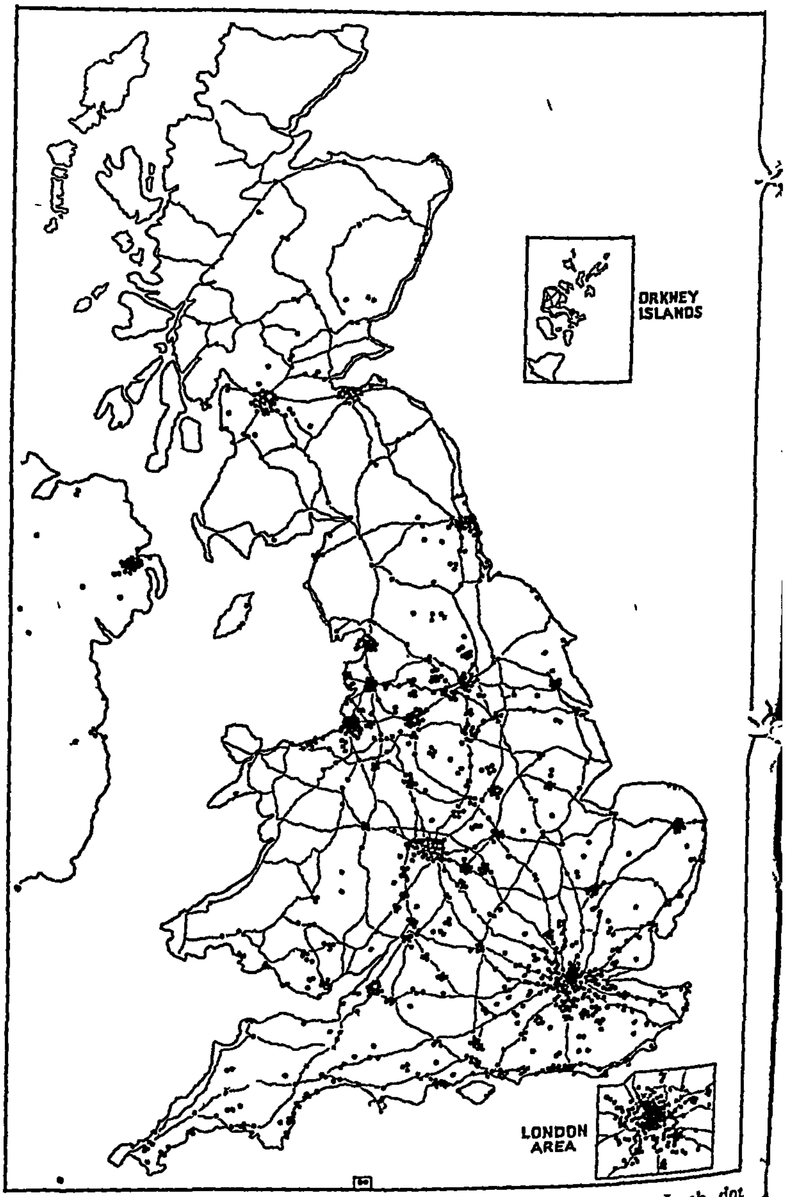
Birmingham —Warwickshire, Shropsh Herefordshire, Worcestershire St and Northamptonshire

Sheffield Lincolnshire

Leeds — Riding)

Manchester —North and East Lancashire (East of the London Glasgow road A 6) East Cheshire Westmorland

Liverpool —South West Lancashire, West Cheshire, North Wales and the Isle of Man



Foundation members of the College of General Practitioners Each dot represents a member The dots in the small square labelled "London" represent members in London additional to those shown on the larger map (Based on an Ordnance Survey map with the sanction of the Controller of H M. Stationery Office, Crown copyright reserved)

THE LANCET

LONDON: SATURDAY, MAY 2, 1953

The Medical Defendant

NEWSPAPER headlines and correspondence columns indicate that medical practitioners are increasingly being made a target for claims based on allegations of negligence. Let it be conceded at once that, if a surgeon or physician injures patients by his carelessness or incompetence, he is not to be shielded from those legal remedies to which his patients are entitled. But, if he honestly does his best, employing at least such reasonable care, skill, and knowledge as the law is content to expect of him, he ought not to be harassed by plaintiffs as if he guaranteed the accuracy of every diagnosis, insured them against every accident or setback, and promised that every operation would result in permanent cure.

How can we explain this undoubted increase in the litigation against the medical profession? Are those observers correct who ascribe it to the coming of the National Health Service? Is it an inevitable feature of the new régime in which everybody has a right to medical care and the members of hospital staffs are known to be paid instead of giving their services for nothing? Are men and women becoming so health-conscious that they demand too much from medical science? Has the replacement of the old system of voluntary hospitals induced an exaggerated estimate of the resources of the State? Are patients encouraged to go to law because they read of the heavy damages already awarded to others? Does the general preoccupation with football pools lead people to try their luck in a different field? Are they backing their fancy that, whatever one doctor has done, another doctor will say it would better have been done differently? It will not be forgotten that there is now another national service besides that of health. Although the Legal Aid and Advice Act is not yet fully operative, the State-aided plaintiff has his free run. An ordinary litigant often takes advantageous advice to settle his case before the parties get into court; but State-aided litigation tends to be fought to a finish without compromise. An ordinary plaintiff is in some measure controlled by certain procedural restraints. The rules allow a defendant, while denying liability, to pay into court a sum which he says is sufficient to satisfy the claim; the plaintiff, if he decides not to take out the money but to continue his action, runs the risk that, should he finally recover a less amount, he must pay the costs incurred by his unjustified persistence. No such check deters the State-aided plaintiff. Why should he break off the fight? Costs mean nothing to him. Apart from all these questions, a defendant who is a medical practitioner nowadays faces another embarrassment. The hospitals, if his work is done there, now find themselves liable in damages as his "employers." The patient who complains of some alleged negligence in the ward or the operating-theatre will sue both the hospital and the practitioner. If so, the hospital may seek to put all the blame on the practitioner, so that he finds himself attacked not only by the plaintiff but also by a fellow defendant. These conditions, of course, mean more anxiety for those responsible for medical defence. They also mean, as commentators have not been slow to point out, that the practitioner, if increasingly menaced by the threat of writs for damages, may incline to play for safety when a bolder course might be to the patient's advantage. Though care and caution are virtues, more harm than good will be done if doctors become obsessed with the need to cover themselves against criticism. For one thing the resources of the service will be wasted by keeping patients in bed unnecessarily long and by subjecting them excessively to radiological and other examinations.

No other profession is comparable with that of medical practice. Solicitors, it is true, have from time to time been attacked in the courts on the ground of their professional misconduct; they contribute to a statutory Compensation Fund from which a client's losses, if due to a solicitor's dishonesty, can be recouped. Solicitors are occasionally sued on the ground of negligence, but fraud has more often been the basis of the proceedings. A doctor has not the same temptation to financial malpraxis. The special element in his daily work is the risk and danger to life and health. "There is always a chance," said the Lord Chief Justice a year or two ago, "that, without negligence on the part of anybody, some unfortunate result will happen, sometimes fatal. Any person who submits himself to any surgical operation is voluntarily submitting himself to a risk. No practitioner is an insurer that no accident will happen. He does no more than profess and undertake to use ordinary skill and care." Lord GODDARD was delivering judgment in a case where the "unfortunate result" had followed an injection. His words would be equally true of any surgical operation and any medical treatment. How is that truth to be taught to the public?

Malignant Change in Vitro

A CHANGE from normal to malignant during the propagation of cells in vitro was first recorded by EARLE.[1] In a culture-medium that included methylcholanthrene (a powerful carcinogen) connective-tissue cells underwent an irreversible morphological variation which had previously been noticed by EARLE and VOEGTLIN.[2] On inoculation of subcultures into living animals the cells continued growing and gave rise to malignant tumours. At the same time a most unexpected result was encountered: fibroblasts derived from the same source but propagated without the carcinogen sometimes underwent the same morphological variation, and on inoculation these also gave rise to malignant tumours. Chance

2. Earle, W. R., Voegtlin, C. *Amer. J. Cancer*, 1938, 34, 373.

experiments lasted only three or four weeks, but they were repeated on several occasions during many months The best opinion at the moment is that there would be a deficiency of calcium in the national diet of 30% if we did not add to the flour

Dr STROSS Is the Minister aware that no one denies the validity of the specific experiment which he mentioned but that recent research has shown that chalk in flour is not needed, for the human body adapts itself to the increased phytic acid which is found in wholemeal flour ?—Major LLOYD GEORGE As the hon gentleman appreciates, this is a technical matter While I should be only too happy to discuss it with him, I think that it would be far better if he discussed it with someone with greater knowledge than I possess

Flour-improvers

Dr BARNETT STROSS asked the Minister of Food whether he now recognised vitamin C as a flour improver, and how far his investigations showed this substance to be harmless for such a purpose —Dr CHARLES HILL replied I share the hon member's desire for a speedy conclusion of the investigations which are in progress, but he will understand the time that such scientific inquiries usually take On the face of it vitamin C seems a reasonable and hopeful proposition but the investigations are not yet complete

Hospital Costs in Scotland

Mr WILLIAM ROSS asked the Secretary of State for Scotland the current average daily cost of maintaining a patient in hospital —Commander T D GALBRAITH replied The returns or 1951–52 show an average cost per patient over all hospitals of *21s 5d* per day

Replying to a further question, Commander GALBRAITH said that in 1952 and 1953 just over £1$^1/_2$ million had been allotted for hospital building work and just over £1 million for essential maintenance

Scottish Tuberculous Patients in Switzerland

In answer to a question, Mr JAMES STUART, Secretary of State for Scotland, said that under the National Health Service 195 tuberculous patients from Scotland were receiving treatment in three sanatoria in Switzerland The average daily cost of treatment was about *30s*, or *34s 4d*, allowing for transport and incidentals such as dental treatment The average daily cost in Scottish sanatoria was about *23s 6d*

B C G Vaccination

Mr JOHN RANKIN asked the Minister if he would extend the use of B C G vaccination to include school leavers —Commander GALBRAITH replied It is proposed in the near future to issue advice to all local health authorities on the extension of B C G vaccination to children about to leave school

Mr ARTHUR WOODBURN Are we to take it from the answer that the Department is now satisfied that B C G is effective and that advisory scientists are satisfied that it is quite safe and reliable as a preventive for tuberculosis ?—Commander GALBRAITH I would not go so far as that, but we believe that trials are far enough advanced to enable a general extension to school leavers 14 out of the 55 local authorities in Scotland have already been specially authorised to provide vaccination for school leavers

Replying to further questions, Commander GALBRAITH said that as there was no difficulty in getting adequate and satisfactory supplies of vaccine from abroad, it had not so far been considered justifiable to incur expenditure on manufacture in Scotland At the moment the vaccine was costing £600 a year One of the biggest manufacturers in this field in this country would undertake production of the vaccine at short notice if necessary

Shortage of Nurses for Mental Deficiency Institutions

Replying to a question, Commander GALBRAITH said that some 30 additional nurses were required to staff the 141 unstaffed beds in Scottish mental deficiency institutions Additional accommodation for mental defective patients was, however, needed and various developments were in view for which considerable numbers of further nurses would in due course be needed

Health Visitors

Replying to a question, Miss HORNSBY SMITH, parliamentary secretary to the Ministry of Health, said that on Dec 31, 1951, the number of health visitors employed by local health authorities (counting two part time as roughly equal to one whole-time) was 0 9 per 10,000 of the population

In England Now

A Running Commentary by Peripatetic Correspondents

COUNSEL for the prosecution in a recent case suggested that a doctor gave "dangerous advice" when he said that he could "find nothing wrong at the moment" If the medical profession takes this to heart we may soon hear conversations on the following lines

Patient Tell me doctor, you don't think it's anything serious do you ? I'd rather know

Doctor (LL B, M.R C P) Hmm, I should rather hesitate to be as dogmatic as that I cannot be absolutely certain, without the performance, in duplicate, of certain test or tests, as to what is or will be the true nature of your alleged illness We shall be safest if we call in two specialists [*Specialists, both* Q C, L M S S.A, *arrive*]

This, gentlemen, is Mrs Litigious She alleges that she experiences er let me quote her signed testimony "headache"

After cautioning the patient that anything she says in her history will be recorded on tape machine for possible medico legal purposes later, the specialists take her history and examine her The doctors then retire to discuss the prognosis.

Well Symes old man, what's going to happen in this case ?

Oh I think we are going to be all right here, it's pretty well wrapped up By the way could you lend me an Investigation Refusal Form ? She's unlikely to want the full Without Negligence drill for headache We always advise burr holes in the skull nowadays, since that case where the ventriculograms were omitted

Ah, sad case that, heavy damages No we can't be too careful You never know what a patient will do As my old teacher used to say "If you know your Law you know your Medicine" Remember his book on *Litogenesis* ? Classic Should be in every doctor's brief case and on every doctor's desk Treatment in this case had best be on expectant lines We mustn't run the risks of supplying her with drugs.

But as a matter of cold fact a patient did say to me yesterday "Tell me doctor what you think I'd rather know I won't hold it against you"

* * *

I have been looking again (as the politicians say) at the Doctrine of Reminiscence in Jowett's admirable translation of Plato All that stuff about education being a drawing out and not a putting in, as quoted by Jeeves and other scholarly types, takes a bit of swallowing We are all tired of hearing that the toddling Mozart was already composing song hits at the age of five, and how that little swot Macaulay could get a *Times* leader by heart by reading it through once In most of us such virtuosity seems to be painfully and curiously lacking To feel, however, that it is all there even if we can't get at it, is immensely comforting and inspiring Whenever I can't remember the dose of the latest wonder drug, I reflect that what I don't know about, let us say, the differential calculus, astrophysics, Syrian dialects, and conversational Chinese is probably not worth knowing

* * *

The only real disadvantage that I can see to living in a cave would be the lack of a front door No doubt the local cave-agents extolled well-situated, sheltered, desirable, well-built caves in rural surroundings, secluded yet not isolated, with beautiful aspect and open views. But for my taste these would have been all too open, and the nightly chore of stoking the home fire burning in the entrance hall would have been irksome, even though it did keep the wolf from the cave No, give me a proper front door like the one behind which I grew up Every night it was shut with solemn ritual Two heavy bolts were shot, a large key turned, the hasp slipped over, and finally a huge iron chain was fastened across as if to make assurance doubly sure This done, everyone could sleep in peace, heedless of whether the back door had been left locked or unlocked according to the caprice of the cook

The heavy, studded oak doors of earlier days were strong, with hinges of wrought-iron a yard long and barred inside by a sapling There is no fairer tribute to the Queen's peace which we all enjoy than the disappearance of these fortifications from new buildings faults, however small, must first be corrected. Much can be achieved even where the nipple is at first so retracted that correction seems well-nigh impossible; the nipple shields designed by WALLER [1] for wearing during the antenatal period are effective even when there is a severe anatomical fault. In the later weeks of pregnancy the daily manual expression of colostrum seems a reasonable practice, to prepare the breasts for lactation and to keep open, and even to open up, the milk ducts. Women taught to do this can help themselves when engorgement threatens; this reduces pressure on the midwifery staff, who then have more time for cases of serious engorgement. Furthermore, lactation will have a better start before the mother leaves hospital; and so she will be very much more likely to continue breast-feeding at home, and to find it satisfactory. Satisfactory lactation cannot be said to be fully established until the nursing or draught reflex is fully conditioned, and in the young primipara this reflex may take a month or so to become established; its inhibition or delay by pain and engorgement needs to be more generally recognised. When engorgement is severe, the breasts should be well supported and feeding temporarily stopped; stilbœstrol in doses of 5–20 mg. helps in the control and probably does not inhibit lactation, though it may delay it temporarily. In less severe cases gentle expression of the breasts relieves the fullness and engorgement, especially around the areola, and so allows the baby to get the nipple well into his mouth and suckle normally. Pain on suckling is a bar to nursing until the nipples are healed.

No less important than antenatal preparation for lactation is a careful aseptic technique in the lying-in period; and infection, where it does set in, should be treated at once with penicillin or aureomycin, before it has passed beyond the stage of cellulitis.[2,3] The organism most often responsible for mastitis is *Staphylococcus aureus*,[4] though others are sometimes found alone or in conjunction with it. Mastitis is favoured by stay in hospital; and when the carrier-rate for staphylococci among the hospital staff or visitors reaches a certain level, epidemic outbreaks of mastitis are likely to ensue unless very strict precautions are taken. Opinion on the mode of infection has varied; sometimes the baby has been regarded as the main agent, and sometimes the environment and hospital personnel. In Germany during the late war it was thought that forcible stripping of the breasts occasionally caused trauma and that infection could take place with organisms circulating in the blood.[5] It seems certain that milk stasis promotes the multiplication of any infecting organism that may be about.[6,7]

A low incidence of mastitis goes hand in hand with successful breast-feeding; and for this reason, if for no other, everything possible should be done to increase the proportion of women who successfully suckle their young. Further progress in the prevention of mastitis calls for close coöperation between the antenatal, lying-in, and postnatal services.

MAPS AND MEDICINE

IT was a map drawn by his young stepson that stimulated Robert Louis Stevenson to write *Treasure Island*. Looking at maps can revive memories of past holidays and work-places and raise hopes of traveller's joys to come. There may therefore be pleasant associations at the back of one's mind when thinking about the use of maps in medicine.

The spot map which John Snow drew of cholera cases in 1854 showed how they were concentrated round the Broad Street pump in Soho. His investigation is recounted, and his map reproduced in the new edition of *Rosenau's Preventive Medicine and Hygiene*.[1] By using Snow's work on cholera as a model for teaching students the Baltimore School of Epidemiology has honoured his achievement, as did Underwood [2] in this country. Spot maps are used routinely in the investigation of epidemics. Recent examples of their use in poliomyelitis,[3–5] infective hepatitis,[6] and influenza [7] show how they can reveal a geographical spread and draw attention to the "odd cases out" which often repay close investigation by providing clues about the mode of spread of infection. Moving, to borrow a phrase from Prof. John Gordon, from "parish pump epidemics" to the study of pandemics over "several centuries and across the seven seas," there are maps of the distribution of poliomyelitis [8] which show that these can summarise the enormous number of data in the records of national and international health organisations.

A further stimulus to the use of maps in medicine is provided by the *Climatological Atlas of the British Isles*.[9] The maps in it are models of clarity and set out vividly the information collected over many years by many observers, a large proportion of whom are amateurs. The amount of detail will surprise those who do not know much meteorology. Thirty-year averages of daily means, maxima, and minima for the year and for each month are mapped for barometric pressure, temperature, rainfall, humidity, and sunshine. There are also data about daily variations of temperature, about wind and snow and frost, and about record rainfalls and droughts. Materials are here for testing any hunches doctors may have about the effects of the weather on their patients and also for studies of the sort proposed by Dr. Jacques M. May under the title of Medical Geography.[10] The necessary medical data are in the reports of the Registrar-General and of medical officers of health and in recent studies by the Social Survey, by regional hospital boards, and by general practitioners. There is here a vast field for studies which would be in the lineage of *Airs, Waters and Places* and *Historical and Geographical Pathology*. Recent papers on the influence of absolute humidity on respiratory infections [11] and on the relation of variations in temperature and humidity to epidemics of poliomyelitis [12,13] encourage the belief that valuable results would accrue.

The study of interregional and international variations in the incidence of disease and death has been extended

predictions based on these For example, we might assume that general practice is to continue in its present form, or alternatively that group practice (specifically defined) is to be promoted over a period of x years Acting on these or other assumptions, reasonable predictions are possible There is an advantage to making more than one prediction based on more than one premise

Our American cousins are the world's best collectors of data, calculators of national requirements, and "projectors" into the future In most detailed and elaborate fashion they have "worked out" the need for doctors in the U S for the year 1963, and have correlated this to the needs of medical education They have even gone so far as to attempt to budget on this basis In so far as they have had to deal with the amorphous mass of totally unplanned medical service and "free trade" medical economics, their task is much harder than that confronting us in Great Britain If we wish, we can learn a great deal from them as to what to do, and what not to do, in this regard That the American medical profession has recognised this need for assessment of "doctor requirements," without the stimulus of a planned medical service, is itself significant They have shown us that it is possible and practical to establish certain premises and then to make reasonably accurate predictions of need They have even been kind enough to show us some of the premises from which we should *not try to work for example, straight doctor/population* ratios without consideration being given to important modifying factors The big U S cities are a working demonstration of the bad effect of over doctoring and over competition on medical morale, ethics, and performance But that is another story

The N H S is itself our guarantee that we will never reach the high point of over doctoring that characterises some areas of American medicine, but we cannot afford even a degree of this The cost in both professional and financial terms is enormous What we must grasp, and act on, is that in a planned medical service serious over-doctoring (or under doctoring) can be prevented, or if *present and detected* early can be cured If not detected, either of these can be as disastrous as any other form of malignant growth The key to this problem is a careful assessment of needs

The newly formed College of General Practitioners, as well as the Medical Practices Committee, could interest themselves *in this problem* with great benefit to everyone

JOSEPH S COLLINGS

UTERINE CANCER AND VAGINAL SMEARS

SIR,—It is surprising to read a leading article in your journal (April 18) which seems to favour the partial conversion of gynæcological outpatient departments to "cancer prevention clinics" The accurate diagnosis of lesions of the breast and rectum is one of the most difficult problems facing the general surgeon Gynæcologists are not competent to undertake this work, even if they were they could only do so by neglecting their gynæcology

Because the misapprehensions in this article are widespread, it may be desirable to comment on a number of the interesting points raised

The correct diagnosis and treatment of cancer requires considerable experience and knowledge Doctors with this training are in very short supply all over the world, and their services must be used to the best advantage

"Cancer prevention clinics" have developed in parts of the U S A in connection with the cancer education campaign Their object is to detect "symptomless cancer"—i e, to bring the cases to suitable treatment at a stage when good results are probable Observation satisfied me that "the mental and physical trauma in borderline cases, eventually found to be free of cancer" is greatly exaggerated I did see a few very unfortunate examples of this, but I was satisfied they should be attributed to lack of training in the doctors, not to the "cancer prevention clinics" as such The steps to be taken by a gynæcologist to diagnose or exclude carcinoma of the uterus are definite, precise, and reliable A good gynæcologist will not create neuroses, even if he is much afflicted by neurotics

Early cancer is *difficult to diagnose* American experience shows clearly that an education campaign will bring the patients to the doctors earlier, often much earlier Unfortunately the medical profession as a whole is not able to diagnose these early cases as well as it should, and the proportion of doctors' errors has therefore risen considerably This is very serious because the delay due to the patient alone is of the order of 12 weeks, but after reassurance by the doctor it is 56 weeks Most patients think we know more than we do, and they do not return until the error is painfully obvious

A good cancer campaign would not begin with the general public, as in the U S A, but would proceed in three definite stages (1) establishment of competent tumour clinics in all our major centres (the various types of consultant required to staff these clinics, and the necessary diagnostic departments, cannot go to cottage hospitals, &c), (2) education of general practitioners in the correct use of tumour clinics, and (3) education of *the general public to make use of their suitably trained* family doctor—he should be our "cancer prevention clinic"

About half the cancer patients are far from hopeless if well managed when first seen There is no such thing as the "cancer specialist," coming along and working wonders after early bad management

The figures you quote of deaths from malignant disease do not represent the true incidence of the different forms of cancer Figures from my disease index of pathologically proved cases (surgical plus necropsy material) are open to the same objections but they are similar 2222 cases of six forms of cancer of current interest are composed of tumours of the breast (807), uterus (369), *colon* (319), rectum (300) (1 7 males to 1 female), stomach (220), and lung (207)

Because good results may be obtained in the treatment of carcinoma of the colon and rectum the gynæcologist would have to diagnose the former as well as the *latter* If he has to spend "some 500 hours of work necessary to reveal one carcinoma" of the uterus (a statement far from true in the gynæcological outpatient department as distinct from the "cancer prevention clinic"), he would have to spend at least 1500 hours to diagnose one carcinoma of the rectum Lack of training and boredom would almost certainly make him miss that one, hence he would probably do far more than 3000 hours for each "positive"

For routine hospital investigations we now consider the cytology section just as *essential as the* hæmatology, bacteriology, and biochemistry departments It is foolish to say biochemistry is more important than hæmatology, and equally foolish to say cytology is more or less important than the other divisions

The steady growth in demand for vaginal *cytology* was really all we needed to prove its value When we passed our 5000th smear some months ago I nevertheless asked the gynæcologists to assist me in determining the value of the method

The gynæcologist does far more than *diagnose* and treat cancer, likewise the merits of vaginal *cytology* are not confined to cancer work With *minor* variations we agreed that its value was, in order of importance (1) diagnosis of cancer, (2) diagnosis of trichomonas infection, for which it has proved the *method of* choice, (3) rough estimation of the œstrone *level*, (4) bacterio

The case described by Griffiths and Gilchrist, and other reported cases where abnormal blood-protein was excessive, have been associated with liver disease. Cryoglobulinæmia has also been reported occasionally in disseminated lupus,[1] in rheumatoid arthritis,[2] and in polyarteritis nodosa.[3] Several workers have found a high proportion of sera positive for cryoglobulins in subacute bacterial endocarditis [1 4 5]; and now Dreyfuss and Librach [2] have found small but definite amounts in 42 out of 50 cases at some time during the course of this disease. Hyperglobulinæmia was present in most sera throughout the disease; but cryoglobulinæmia was independent of this, and appeared to be related more closely to increased euglobulin content. Positive findings were also independent of the species of the infecting organisms, which included staphylococci, non-hæmolytic streptococci, and hæmophilus strains, as well as *Streptococcus viridans*.

The production of cryoglobulins, therefore, seems to be a special type of reaction in a predisposed host, rather than a response conditioned by a specific bacterial stimulus. If this is so, it would be of interest to know whether cold-precipitating globulins are formed in endocarditis lenta where the primary heart lesions are congenital and not rheumatic. A distinction emerging here might throw light on more than the academic significance of cryoglobulins.

MEN AND MANNERS

> "In dealing with human beings, science is not enough; you must also have good manners."

Lord Percy of Newcastle, in his presidential address last Tuesday to the Royal Sanitary Institute's congress at Hastings, thus neatly stated a perennial truth, and added that it is good *public* manners that are the hardest to learn. Dr. Richard Scott developed this thought further in his paper on the training of medical students in the practical aspects of preventive medicine. Coördination in the three great arms of the health service—the hospital and specialist service, the local-authority service, and the general-practitioner service—depends among other things on human relationships, and more especially on "that surprisingly complex form of human relationship" operating between professional people. In medicine it should not be as difficult as it sometimes seems to foster sympathy between colleagues in different branches; for the consultant, the medical officer of health, and the general practitioner trained in the same medical schools, and were for six years nourished in the same traditions and curriculum. Edinburgh University has always tried to give its medical students a sense of the indivisibility of medicine, by sending them out in their final year to see patients as the general practitioner sees them. At one time students used to attend the public dispensaries; but of late years one of these dispensaries has been developed into a general practice under the National Health Service, staffed by two doctors, a public-health nurse, an almoner, and a secretary, all of whom are employed by the university; and the students learn about general practice from this team. Dr. Scott described the original unit some years ago in our columns,[6] but since that time a second unit has been added, largely thanks to the help of the Rockefeller Foundation.

At the congress he was able to report some of the effects on students of attending these units. They graduate from listening-in during the doctor's surgery to the responsible care of patients, and more particularly to care of a family (using the clinic doctor as consultant); and they join in the daily case-conferences where the medical and social treatment of the patient are discussed and agreed on by the team. Dr. Scott noted that the student, when he first comes, is often disappointed that "major, dramatic and urgent pathology is so relatively uncommon"; and moreover he is disturbed to find how often it is impossible to reach a final satisfactory diagnosis. His disapproval, however, gives way to a second phase in which he becomes increasingly impressed with the psychosomatic aspects of disease, and sometimes declares that general practice "is really psychiatry." He begins to talk more freely to patients, and then to make his first home visits, where a new lesson comes home to him. Most of the patients are poor, and he becomes obsessed with the economic and social components in ætiology: his doubt of the powers of medicine to help much plunges him into therapeutic nihilism. Return to the wards is some corrective for this, but he is now able to receive his clinical teaching with a broader, more balanced mind. One message passed on to him during his last weeks at the unit is that as a practitioner he will have a duty to keep his colleague, the medical officer of health, informed of the medicosocial problems presenting themselves in general practice, and to work alongside him as a field intelligence officer. But his chief gain is in the insight he acquires into patients as people, and his sudden grasp of the fact that this girl in her 'teens, brought by her mother, is not someone who will pass in and out of his ken by way of a hospital bed, but the same girl who will be coming to him for antenatal care in ten years' time, and who in twenty years' time will be bringing her own daughter to him for advice. He is, in fact, not just "seeing a case," but making a lifelong acquaintance with whom he must collaborate.

As Lord Percy reminded the congress at the outset, the true base of operations for good family doctoring is not in any system of model health centres, but in the homes of the people.

NEEDLE BIOPSY OF THE LIVER

SINCE the introduction by Roholm and Iversen, of needle biopsy of the liver[1] its value in the study of hepatic disease has been repeatedly demonstrated. At first it was justifiably regarded as carrying considerable risk, but common-sense precautions have rendered it "a most useful procedure with a gratifying degree of simplicity, efficiency and safety."[2] It is, in fact, indispensable for accurate diagnosis in many cases in which disease of the liver is suspected. Its value is clearly shown in Christian's report[2] from New Orleans. In as short a period as eighteen months, needle biopsy was found necessary in 91 patients; and of the 73 in which it was performed purely for diagnostic purposes, the prebiopsy diagnosis was shown to be wrong in 35 cases. In other words clinical and laboratory methods combined gave a correct diagnosis in only half the cases investigated. Apart from its value in the diagnosis of diseases of the liver itself, needle biopsy has often provided definite evidence of conditions difficult to diagnose, such as the chronic granulomata, including brucellosis, sarcoidosis, and histoplasmosis, as well as miliary tuberculosis and non-specific granulomata in patients with pyrexia of unknown origin.

The chief contra-indication to aspiration biopsy is any condition in which there is a tendency to bleed. Fortunately this can often be overcome by preliminary treatment with vitamin K or by a blood-transfusion. In severe or prolonged jaundice from biliary obstruction, there is also some risk of bile peritonitis from perforation of one of the greatly dilated intrahepatic ducts. It is also wise to exclude patients who may have a subphrenic or hepatic abscess or other local infection that might be the proportion of registrars to consultants which will provide for replacement and "healthy" competition is not even remotely related to the present staffing of hospitals, particularly in departments of general medicine and surgery

In the bad old days hospitals were staffed by housemen and by "consultants," of whom many were also in general practice Chief assistants were found mainly in teaching hospitals, and smaller hospitals would have a R S O and perhaps a R M O Yet there was still competition for specialist appointments Now every hospital is littered with registrars, and the consultant unblessed with at least one is small beer indeed

Dr Forrester and Dr Walton suggest that displaced senior registrars be encouraged to pursue their dwindling hopes from post to post Rather than prolong this dismal muddle, would it not be kinder to give their ambitions the *coup de grâce* forthwith, by Purge or Inquisition ? Or, alternatively, to eliminate all new registrar appointments except for those men genuinely in training for prospective vacancies, and spend the salary of £890 on paying a new consultant for the appropriate number of sessions ? There are many who would *rather* be indigent surgeons than poor G P S But perhaps the present part-time consultants would not approve

RENAL DUCTS OF BELLINI

SIR,—In reply to Mr Ross (April 18), I cannot see how the use of 'Neoprene,' post mortem kidneys, and an unnatural physiological way of approach can give the conclusion of irrefutability to his experiments If this were so it would be logical to expect that before obtaining a back-flow retrograde pyelogram it should in every case be possible to inject the Bellini ducts, but, as is obvious from radiological evidence, this is not so

I would add two observations firstly, the finding of uric acid precipitate in the kidneys of an eleven-month old girl who died from a non-kidney disease, showing that its elimination is not as easy as has been accepted, and, secondly, if comparative anatomy is of some value to the study of human functions, it may be of interest that the kidney of the cat, which has only one pyramid, has no Bellini ducts at all, and the larger tubules are orientated parallel to the renal pelvis, and not perpendicular to it

Booth Hall Hospital
Manchester

F DURAN-JORDA

DISORDERS OF MOTILITY OF THE SMALL BOWEL

SIR,—The cases described by Mr. MacPhee (April 4) and by Dr Frankel and Dr Moore (April 18) both illustrate the development of ileojejunal insufficiency following Polya type gastrectomy These cases are occurring with increasing frequency Having recently studied several such patients in some detail, we are inclined to attribute this disorder of small-intestinal function to the presence of a cul-de sac In one of our cases the operative restitution of the normal duodenal pathway led to complete cure of the steatorrhœa and wasting Megaloblastic anæmia, as found in Frankel and Moore's case, is due to a vitamin-B_{12} deficiency and occurs only rarely Possibly it is due to the same mechanism that causes megaloblastic anæmia in man and other animals after the formation of intestinal cul-de sacs

On searching through the literature we have found a large number of cases of steatorrhœa, creatorrhœa, and wasting which have developed after the formation of intestinal cul de-sacs After a Polya-type gastrectomy this may occur, especially if the afferent loop is long and antecolic In all cases in which it has been tried, restitution of the normal continuity of the gut has cured the condition

It is possible, as Mr MacPhee suggests, that th ileojejunal insufficiency is associated with a refle disorder of intestinal motility, but there must also b a considerable disturbance in the chemical, physical and microbiological environment within the intestine

Reporting our own observations and experiments i a paper shortly to appear, we have used the comprehensive term "intestinal cul de sac phenomena" t describe the syndrome

Bristol W M CAPPER

CONTRACEPTIVE TECHNIQUE

SIR,—We have noted with some misgivings the appearance for some months past in your journal of commercial advertisements concerning a certain contraceptive jell which is recommended to be used "without a diaphragm" or the simultaneous employment of that or other barrie pessary the implication being, of course, that this jelly method alone is a safe one

Experience at the clinic of the Society for Constructive Birth Control over the past thirty years has convinced us that for effective contraception in all cases the use of a mechanical barrier to the entry of spermatozoa into the cervical canal, as well as a chemical substance (preferably a suppository with a greasy base) to inactivate the spermatozoa, is essential to reliable contraception Evidence of the repeated failure when one method alone has been used to prevent fertilisation is continually accumulating from the case histories of patients who attend this clinic after other methods have failed them

We believe that this opinion is shared by most of the clinics concerned with birth-control in this country, and we are therefore dismayed to find that a purely commercial institution is able through your advertisement pages to promulgate claims which are entirely at variance with the majority views of scientists in this country who have special knowledge of this aspect of preventive medicine

BACT COLI IN THE CAUSATION OF INFANTILE DIARRHŒA

SIR,—The isolation in Japan by Prof Tohru Ogawa and Prof Jiro Ogawa (March 21) of *Bacterium coli* of the serological types 0 111 B4 and 0 55 B5 from infants suffering from diarrhœa and vomiting provides a further instance of the association of these organisms with this disease

That one of these two serological types may predominate over the other at different periods in the same area has already been demonstrated,[1] and is again illustrated by the results of bacteriological examination of rectal swabs taken from infants on admission to the gastro-enteritis unit of this hospital Thus, during the past four months, December, 1952, to March, 1953, *Bact coli* 0 55 B5 was isolated from 24 out of 90 children admitted, and *Bact coli* 0 111 B4 from only 4 These results contrast with those of *1949* when *Bact coli* 0 111 B4 was isolated from 38 of 153 admissions and *Bact coli* 0 55 B5 from 12 It was found [2] that 9 of the 12 *Bact coli* 0 55 B5 strains isolated in 1949 possessed H6 antigens (thus conforming in flagellar type to the strains originally isolated in Aberdeen [3 4]), 2 possessed H2 antigens, and 1 had H7 In the current series, all of the 24 *Bact coli* 0 55 B5 strains possessed H2 antigens The infants from whom they were isolated came from various places in North and East London,

THE FAMILY

CONFERENCE IN LONDON

OVER 500 people assembled for the British National Conference on Social Work, held in London on April 16–18 under the chairmanship of Sir WILSON JAMESON, with The Family as its comprehensive theme.

The Family as a Social Institution

Prof. RICHARD TITMUSS remarked that the family, which used to be a private affair, had now become a public institution; and since the health and stability of the community were recognised as depending on the health and stability of the family, even the quality of its internal life had become a matter of public concern. As society made the business of being a parent more a matter for expert advice, parents became more self-conscious and more anxious. Professor Titmuss suggested that there was a risk in seeking to impose general standards of child care and health education throughout a community when these might only be assimilable within certain strata of society, with the result that the self-confidence of parents might be seriously disturbed and they might fade into a state of inert irresponsibility. He pleaded for re-examination of the training of all professional persons directly concerned with the health and welfare of the family.

In drawing attention to the implications for the family, and in particular for the mother, of the decline in the birth-rate and the emergence of the small family as the typical modern family unit, Professor Titmuss referred to "problem families" as apparently less numerous than before the war and recruited from the rapidly dwindling group of large families. "They are reproductive deviants;" as such they might soon become anthropological curiosities.

The revolutionary reduction in the time devoted by women to bearing and nursing children compared with the last years of the 19th century, estimated at $3^{1}/_{2}$ as against 12–15 years, and the 35-year expectation of life after 40 years of age, by which time the business of child care was largely over, led Professor Titmuss to urge the need for re-examining woman's rôle in society. Figures for married women in employment, now apparently at a peak, also suggested a shift in social practice to which social policies should bear some intelligible relation. Of all mothers with children 10% worked outside the home during the first 5 years of marriage, and the figure increased to 24% when the marriage had lasted 15 years. We ought to know why this was so.

Professor Titmuss disposed of the popular belief that most divorces occur in the first few years of married life: he declared that the rate of divorce in the early years of marriage was comparatively insignificant (less than 30 in every 100,000 couples), and that the rate became much higher after the marriages had lasted 10–20 years.

Throughout his address Professor Titmuss effectively illustrated his main thesis that the family has never been a static institution, but has continually evolved in response to internal and external forces of change.

Statutory and Voluntary Effort

In the absence of the Minister of Health, Miss PATRICIA HORNSBY-SMITH, parliamentary secretary to the Ministry, testified to the importance of the subject-matter of the conference. She spoke of the vital importance in our social services of a wise combination of statutory and voluntary effort; and, in emphasising the importance of dealing with the family as a whole, she reminded the conference that the three-tier family was still an important unit of social responsibility.

Special Problems

Dr. JOHN BOWLBY made a plea for more biology teaching in the training of social workers; he suggested that this would bring new strength to the study of personal relationships. Like Professor Titmuss he feared that many mothers were disturbed by misleading standardised teaching, and he lamented that our services were not built round the idea that a child's relation to his mother was of first importance. If this fact were recognised we should be less prone to break up the problem family or to spend large sums on caring for sick children away from home. He regarded additional psychological study as essential in the training for social work.

Reports on Discussion Groups

At the final session three rapporteurs reproduced the findings of the twenty-nine groups which during the conference had been engaged in more or less detailed discussion of the main themes. It was clearly impossible for them to reproduce precisely the findings of these groups, or indeed to convey the extent to which the findings were unanimous. Nevertheless it seemed that a large measure of agreement lay behind the reports, which included the following conclusions.

IMPACT OF SOCIAL SERVICES

The family was accepted as a social institution vital to the healthy life of the community, and this healthy life depended largely on the quality of individual relationships. There was a growing feeling against removal of children from their families, including the children of problem families. As to the employment of mothers there were differences of views, and judgment might depend on the reasons for which they went out to work.

Anxiety was expressed that the social standards set by present-day services might require from the ordinary family a response which involved strain. The parent who felt that he or she fell short in a visitor's eyes in matters of budgeting, cleanliness, or child care was the more liable to try to cast responsibility on to the State which seemed to have so much to offer.

There was disquiet, too, at the services that had been enumerated that might lead to disruption of the family group in endeavouring to provide for the homeless, the handicapped, the aged, or children; at the current emphasis and expenditure on curative services; and at the lack of a social policy directly designed to strengthen and support the family.

As a subject for discussion the problem family appeared to have exercised a fascination out of all proportion to its numerical importance. Whatever was done should be done for the family as a unit, always remembering that material standards were here of secondary importance to considerations of emotional and mental stability. The need for intensive personal work over a long period was recognised: such work should be with the family in its own setting, aimed at a standard within its reach and at fostering a relationship of friendliness and trust as an essential preliminary to building up other social relationships.

Discussion of evicted families had given rise to some criticism of housing policies which led to homeless families becoming a heavy financial burden on public funds. There were often alternatives to eviction which should be fully explored. Where evicted families came into the care of a local authority, case-workers might be appointed to undertake individual work and bring in voluntary effort.

SOCIAL WORKERS

It appeared that in discussing the rôle and training of social workers the groups had not been disposed to be

It may be thought impertinent for someone from the South of England to make comments on this situation, but the problem of tuberculosis in the British Isles is surely indivisible

The pathetic housing programme must receive the most urgent attention in Government circles, and, at the same time, the medical and nursing profession in Glasgow should rise to meet the demands of their local population It is essential that the facts should receive the widest publicity in the national press and on the air, in order that there may be quickening of response to this tremendous human need

London N W 10 **Horace Joules**

EPIDEMIOLOGY OF STREPTOCOCCAL INFECTIONS

SIR,—In their very interesting review of the epidemiology of streptococcal infections in your issue of April 11, Professor Dingle, Professor Rammelkamp, and Dr Wannamaker refer to their finding that, in a number of instances, infections due to hæmolytic streptococci of type 12 have been particularly commonly followed by acute glomerulonephritis It is clearly of considerable interest to see whether a similar association can be shown in Britain The Streptococcal Reference Laboratory at Colindale and the regional laboratories of the Public Health Laboratory Service at Cambridge, Cardiff, and Oxford would be very glad to collaborate with pædiatricians or others who may have an opportunity of making such an investigation and to undertake the type identification of group A streptococci that have been isolated in circumstances suggesting that they may have initiated an attack of nephritis

Streptococcal Reference Laboratory

Colindale, London, N W 9 **R E O Williams**

TRAINING OF PHYSIOTHERAPISTS

SIR,—Prominence has been given lately in medical journals to the training of physiotherapists, and we feel that certain points ought to be clarified

Physiotherapists in this country belong to three groups (1) the Physiotherapists Association, (2) the Faculty of Physiotherapists, and (3) the Chartered Society of Physiotherapy The Cope report, drawn up by a committee of nine members, six of whom were in active association with the Chartered Society, whereas the other two bodies were not represented, recommended hospital authorities to employ exclusively members of the Chartered Society, and the first circulars of the Ministry of Health were drawn up in this spirit The injustice of this report, however, has been rapidly realised, and the Minister of Health stated in Parliament on March 19 that the Cope report would not be implemented, and that he would further withdraw the temporary instructions in the Ministry circular referring to the employment of chartered physiotherapists, and make new regulations fair to all associations

We are at a loss to understand this tendency of the Chartered Society to monopolise physical treatment in this country Apart from the fact that it goes against the liberal principles that dominate medical work, nothing has demonstrated the superiority of the members of the Chartered Society over those of other associations of physical-treatment practitioners We must emphasise that hospitals employing members of the Physiotherapists Association and the Faculty of Physiotherapists are perfectly satisfied that the training of members of the association and the faculty is not inferior to that of the Chartered Society

The education plan formulated by the Physiotherapists Association, and supported by education authorities, experienced teachers, and the medical profession, provides for the cooperation of technical colleges and teaching hospitals Physiotherapy training schools should be part of a university, and the physiotherapist's qualification should be a recognised university diploma The real aim is to enable the physiotherapist to take his place as an accepted member of a medical team, receiving alike the support of the medical profession and the confidence of the public

PHARMACEUTICAL ADVERTISEMENTS

SIR,—Could not the British pharmaceutical firms serve the community even further by including in all their copious advertising matter the price of the preparation advocated ? Of course, the resulting reduction in profits would mean less funds for research, but I venture to suggest that, on balance the community would benefit more

Rickmansworth Herts **A W Anderson**

ENLARGED HILAR GLANDS

SIR,—It is to be hoped that your annotation on this subject (April 18) may act as a catalyst, and promote some useful reaction amongst those of your contributors who are interested in a problem which is still very much in the melting-pot

It would be of great interest to know how frequent these cases of asymptomatic hilar-gland enlargement really are in this country, and how they fit in to the broader general picture of hilar adenopathies in young adults It is well known that bilateral hilar gland enlargement at this age is much more common in Scandinavian countries than in the British Isles In recent years large series of such cases have been reported, from Sweden in particular

Lofgren, for example, has made a special study of the question, and he has recently published[1] two papers in collaboration with Lundback, in which 212 cases of "the bilateral hilar lymphoma syndrome" are studied in relation to (1) age and sex incidence, and (2) tuberculosis and sarcoidosis Of these patients, 161 were women and 51 men, and in 113 cases the syndrome was associated with erythema nodosum (107 females, 6 males) The maximum incidence was found in the age group 25–29 In the female group, a *relation to pregnancy and lactation* was observed in some cases

In 100 cases tuberculin sensitivity was absent, even to 1 mg of tuberculin Complications, tuberculous in type, developed in only 1 case A diagnosis of sarcoidosis could be established by histopathological examination on an average in 26 4% of cases, but during the later stages of the investigation, 23 out of 49 cases (47%) were proved to be sarcoidosis

The conclusion drawn is that this syndrome is independent of tuberculosis from the point of view of ætiology The authors interpret it as being a manifestation of sarcoidosis, and more exactly, as the primary stage of pulmonary sarcoidosis

Our own short paper[2] reported 6 cases of bilateral hilar-gland enlargement, all in relatively young women with erythema nodosum In 5 cases the Mantoux reaction was positive, and in the 6th it was negative at 1 in 10,000 There was a history of recent pregnancy in 2 cases No clinical manifestations of sarcoidosis were found, though, if it had been possible to make the intensive search for biopsy material mentioned by Lofgren and Lundback, the result might have been different in some cases

Chaves and Aboles[3] whose paper, entitled Transient Undiagnosed Intrathoracic Lymphadenopathy in Apparently Healthy Persons, you mention, lay down as criteria for their cases the spontaneous regression of enlarged glands and the absence of evidence of pulmonary or other visceral involvement throughout the period of observation From the large volume of material available for screening, coming from

Parliament

British Hospital in Paris

IN the House of Lords on April 22, replying to a question by Lord AMULREE, the MARQUESS of READING, parliamentary under-secretary for Foreign Affairs, said the Hertford Hospital in Paris was closed to patients last year. At that time the difference between regular income and expenditure which had to be met by donations or out of capital had risen from £15,000 in 1948 to £26,000 in 1951, and out of a normal complement of 50 to 60 beds an average of only between 21 and 25 were occupied. Last autumn the Charity Commissioners prepared a scheme whereby £30,000 was to be raised from endowments for the modernisation of the hospital, which was founded in 1871. At the same time Sir Bernard and Lady Docker offered a sum of £30,000, not towards the support of the existing hospital but for the construction of a new Docker Wing of 10 beds for fully paying patients.

Lord Reading added that although remittances for the continuance of British charitable works abroad were normally approved without difficulty, remittances for capital expenditure on new developments must obviously be carefully scrutinised; and one of the points on which the Treasury would need to be satisfied was that the new works would constitute a viable proposition. It was upon this aspect of the scheme that the Treasury felt obliged to obtain fuller information than had been received when Sir Bernard and Lady Docker's offer was withdrawn. He understood that at a meeting of the hospital committee on March 31, the chairman was asked to work out a fresh scheme to ensure the continued existence of the hospital. The Chancellor of the Exchequer would be prepared to consider sympathetically the remittance, both of the capital sum needed for the cost of the new wing and of such future sums as would be required for the maintenance of the hospital as a whole, if he could receive satisfactory assurances that the hospital's income from fees and donations would be adequate for its future needs.

Earl JOWITT hoped that Lord Reading would realise that there was an element of prestige involved in this matter. The hospital had a long and honourable tradition, and in his view it would be a grave misfortune if it had to close through lack of funds. The MARQUESS of READING said that he appreciated this point and that the Chancellor was prepared to consider the situation. At the same time, while not prejudging the matter, it was a serious question whether in present conditions, and with the decrease in the British population in Paris, there was a case to be made for a viable hospital on those lines.

Pharmacy Bill

In the House of Commons on April 24, Mr. JOHN HALL moved the third reading of the Pharmacy Bill, which had passed through Standing Committee unamended. Miss PATRICIA HORNSBY-SMITH, parliamentary secretary to the Ministry of Health, said she was sure that the whole House would welcome the Bill which, although a domestic measure mainly sponsored by the Pharmaceutical Society, tidied up the matter of the two registers which formerly operated for pharmaceutical chemists and chemists and druggists. The Bill was read the third time and passed.

QUESTION TIME

Food Hygiene and Infectious Disease

Mr. G. H. OLIVER asked the Minister of Health what steps were taken to ascertain whether persons employed in the preparing, cooking, and serving of food in hotels, restaurants, and road-side cafés were free from infectious diseases such as tuberculosis.—Miss M. P. HORNSBY-SMITH replied: There is no general power to require the persons concerned to be medically examined for this purpose, and the Minister is advised that the present state of our knowledge does not suggest that such a power would be justifiable as a means of preventing the spread of infection.

National Health Service Inquiry

Dr. BARNETT STROSS asked the Minister to what extent the terms of reference of the committee which was to investigate the costs of the National Health Service included powers to consider salaries paid to medical and non-medical staff, and the economies that might be effected by employing consultants on a full-time basis only.—Miss HORNSBY-SMITH replied: The Minister would certainly not expect the committee to deal with actual rates of pay. For the rest the Secretary of State for Scotland and the Minister are anxious not to hamper the committee in their work by seeking to restrict their field of inquiry.

Doctors and Litigation

Air Commodore A. V. HARVEY asked the Minister what steps he was taking to safeguard doctors from litigation resulting from their work in the health scheme.—Miss HORNSBY-SMITH replied: Officers of the department are at present discussing with representatives of the profession the relations, financial and other, between hospital authorities and their medical staffs when legal actions are brought against either or both.

Tuberculin-tested Milk

In answer to a question Sir THOMAS DUGDALE, the Minister of Agriculture, stated that under the Milk (Special Designation) (Raw Milk) Regulations, 1949, applications received after Sept. 30, 1954, for the issue and renewal of licences to use the designation "Tuberculin-Tested" would only be approved in respect of attested herds. The success of the attested herds scheme had made it possible to add this more stringent test to the present requirements of animal health and hygiene in the dairy. The scheme was going extremely well and we were getting more and more absolutely clean milk in the country.

Calcium Content of Flour

Dr. BARNETT STROSS asked the Minister of Food the number of days involved in the original experiment in 1942, when, after a diet in which 50% of the calories were supplied from flour of 92% extraction, it was noted that absorption of calcium decreased; his reasons for continuing the fortification of bread with chalk; whether, in view of recent research, he would consider revising his policy; whether he had noted the fact that the human body could and did acclimatise itself to high intakes of phytic acid if ingested over a prolonged period; and whether he would now cease to fortify bread with chalk.—Major GWILYM LLOYD GEORGE replied: In the 1942 experiment the subjects were under observation for 21 to 28 days. Calcium carbonate is now added to flour to ensure that total food-supplies provide sufficient calcium to meet nutritional requirements. Flour provides nearly 30% of the total amount of calcium in the diet; and any adverse effect of phytic acid on its absorption is of small importance in relation to that amount.

Dr. STROSS: Does the Minister think that after all these years we should still be tied to one single experiment which lasted only three or four weeks, as a result of which we have been imbibing or ingesting large quantities of chalk in our bread ever since? Has not he been informed of more recent work which shows that phytic acid is not detrimental to human beings and that we do not need to nibble away the cliffs of Dover entirely against a danger which we feel now does not exist at all? Will not the Government look at the matter again?—Major LLOYD GEORGE: We are prepared to look at anything, because this is a matter of tremendous importance to the nation as a whole. It is true that the week in patients in the isolation hospital here Encouraged by the results, I introduced heat and the muscle relaxant drugs to relieve spasm, and by the end of 1949 I had no hesitation in beginning not only passive movement but active exercise as soon as pyrexia had subsided

Final proof of efficacy could be obtained only by comparing patients so treated with themselves as they would have been if otherwise treated—a manifest impossibility I have certainly had a lower-than-average incidence of contractures, and an impressive proportion of my patients have been discharged to their homes, requiring only outpatient physiotherapy and remedial exercises to complete their treatment I have had no case in any way corresponding to that reported by Mr Hyman

I have, however, tried to follow a policy of asking no muscle or group of muscles to bear disproportionate strain. So long as the patient is in bed this is easy, for no limb can be called on to do more than raise its own intrinsic weight, and if the muscles cannot raise the limb from the bed they do not even have to bear that weight In other words, they are not asked to carry a load until they have shown themselves capable of making a reasonable attempt to do so

When the patient gets out of bed, the case is altered and the legs are at once called upon to support the weight of the whole body, even if they are not ready to do so I cannot help suspecting that this may have been the determining factor in Mr Hyman's patient, and that the golden rule, especially in dealing with enterprising schoolchildren and other impatient people, is to keep them strictly in bed, except for tank exercises, until there is evidence that the muscles of the legs are ready to make at least a fair attempt to carry out their normal duties

Myland Hospital, Colchester JOHN D KERSHAW

AUGMENTING KNEE-JERKS

SIR,—However "ludicrous" the traditional methods of augmenting the knee jerks may appear, they are certainly preferable to the method suggested by Dr Hirschowitz (April 25) If, for example, a patient has a one-sided partial paralysis of his lower-limb flexors, then when he pushes into the bed, the degree of reciprocal inhibition of the extensors so produced may, and probably will, produce a spurious inequality of the knee jerks This is one of the reasons for insisting on complete relaxation where possible, however tedious it may be to obtain

Hoddesdon, Herts BARBARA SIMONDS

TRICHOMONAS VAGINITIS

SIR,—I have been interested in the recent articles and letters on trichomonas vaginitis While supporting Mr McCullagh's laudable plea (April 4) for the "gap" seat in lavatories, I think he is being rather hopeful when he says that we could expect cases to be reduced by 90% if the gap seat were universal

For the last four and a half years I have been in practice in North-east India and East Pakistan, where the Eastern squatting position is universal, and in my experience the prevalence of trichomonas infestation there is almost as great as it is in this country Gonorrhœa, of course, is the main cause of infective vaginal discharges, but trichomonas runs it a close second

I am of the opinion that transmission is mainly venereal, with perhaps a small percentage of cases caused by infective clothing During routine prostatic smears, of which we perform very many in a busy outpatient hospital practice, I have come across two instances of *Trichomonas vaginalis* in the resting phase Is it not possible that in the male the parasite lodges in the seminal vesicles or the prostatic ducts without causing any symptoms, and that it multiplies and causes symptoms only in the favourable medium of the vaginal secretions ?

Perhaps observations on husbands of infected women with a series of non infected couples as controls might give a convincing answer to the vexed question—is this mainly a venereal or a non venereal disease, and, if venereal, can any treatment be directed at the husband as well as the unfortunate wife ?

Glasgow J T PATRICK

THE GAP SEAT

SIR,—The correspondence (April 4 and 18) about the value of the gap seat brings back old memories to me, for it was I who first thought of it in 1905 I was at that time R M O at the Lock Hospital for Women Harrow Road We then had the old type of oval lavatory seat, and though the lavatories themselves were labelled *syphilis* and *gonorrhœa*, I soon found that the patients disregarded the labels and used them indiscriminately, leaving obvious signs of use on the front sections of the seats

Cross infection between gonorrhœa and venereal warts certainly occurred, and probably trichomonas also, and I was so worried by this that in the top ward I had a section of the front of each oval cut out and rounded off, thus making a horseshoe shaped seat It was one of those things that once thought of seemed surprisingly obvious The hospital architect saw it, gave it his approval at once, and had the lavatories in all the wards similarly treated

I thought no more of it after I left Harrow Road until some years later when I began to find it was being supplied to other hospitals, and I have never until now troubled to claim any credit for it—it seemed so simple But undoubtedly it is a definite hygienic improvement and probably should be made compulsory in all public lavatories It also has the advantage that the seat need not be lifted by men

Dr Hudson (April 18) suggests that it would be even better still to use the squatting platform one finds in Turkey and the Near East That certainly is true, but we are so conservative in this country that his advice is extremely unlikely to be followed So may I still recommend my gap seat, at any rate until something better is invented !

London, W 1 J JOHNSTON ABRAHAM

CHLORAMPHENICOL BY INJECTION

SIR,—In your annotation last week entitled "Good Sense about Antibiotics" you say that "chloramphenicol is not suitable for intravenous, intramuscular, or intrathecal injection" May I point out that the antibiotic has been successfully administered by each of these routes ? A solution of chloramphenicol in aqueous dimethylacetamide has been widely employed [1,2] both intravenously and intramuscularly A number of reports [3,4] have appeared on the intramuscular use of an aqueous suspension of microcrystalline chloramphenicol As chloramphenicol readily penetrates the blood brain barrier,[5] intrathecal injection is not usually necessary, but as an adjunct to oral therapy it has been considered desirable, on occasion, to use this means of rapidly raising the cerebrospinal fluid level Intrathecal injections, in the form of sterile aqueous solutions, have been well tolerated [6]

One of the few remaining traces is a grille—but in England a grille makes one think of nuns peeping out, whereas in Spain it makes one think of bandits peering in.

A wide panelled Georgian front door, surmounted by a glass and wrought-iron fanlight, is a thing of beauty, and I know one modern door in London, richly black, with silver-plated accessories, which breathes an atmosphere of dignity and calm. But for sheer enchantment look for those doors painted like jewels in vermilion, turquoise, or palest jade. They replace the glowing colours of my childhood days, brilliant in memory with window-boxes, striped awnings, flower-sellers, and monkeys in red flannel jackets, who, with their Italian organ-grinders, brought a Southern sunshine to our streets.

* * *

He was a man after my own heart; an urbane and cultivated doctor with a taste for the arts, exquisite manners, and a kind of quintessential aristocracy. There are wines by nature of royal vintage.

He was principal in our firm of three, and in ten years of intimate association I never saw him ruffled, nor heard an intemperate remark. He had achieved the greatest gift of a family doctor—the envied quality of every man of civilised habits—the power of living *tempo moderato.* The fever and the fret of life passed him by. He was never involved in it.

He was a great reader and a great talker. I never knew a man who relished words more than he did. He responded to a felicitous phrase as a woman to a compliment. And yet there were gaps in this most integrated personality that might puzzle and intrigue his Boswell. He spoke to me only once of religion and that was to claim, with his own characteristic confection of conceit and simplicity, that he considered himself "deeply religious—though bad at being religious."

On the eve of his retirement we were taking brandy together after a dinner en famille.

"In your long years of medical practice have you any regrets?"

"Yes, that I have so seldom, in the Pauline and proper sense of the phrase, *visited the sick.*"

* * *

In the otolaryngological outpatient department of a Dublin hospital recently the surgeon in charge—and a senior one at that—took a patient into the darkroom for transillumination, accompanied by his house-surgeon and a nurse. The lights were turned out and the test completed, when an eerie purple glow was seen in the darkness. On investigation this funereal light proved to come from the dermatologist's ultraviolet lamp, which had been accidentally turned on.

"I see you have a false tooth, sir!" said the nurse, a pert young blonde.

The surgeon looked at his face in a hand mirror kindly provided for him, and saw that his single false incisor shone a bright buttercup yellow.

"Well, I may look a little peculiar, but have you seen yourself?" said the surgeon, slightly shaken, as he handed the mirror back to nurse.

Nurse looked at her face in the mirror, emitted a scream, and fled. She was soon recaptured, and solaced by cups of tea when the fit of the giggles which succeeded the screech of horror had subsided. And the cause? Her eyebrow pencil, which had caused her brows to phosphoresce like two brilliant bars of Neon light in the midst of a jade-green face.

* * *

Your annotation last week (p. 839) on the physiological difficulties of air travel reminds me of the story of the American explorer who made a forced march through a tropical jungle for a couple of days. On the morning of the third day, he found his native bearers sitting about, chatting and smoking their pipes. When he indignantly asked the head bearer why they were not getting ready for the day's journey he was told that the men felt they had left their souls behind them in their rapid progress and must now wait until these caught up.

The poetic young man at our sanatorium now calls the lady doctor who refills his A.P. the Lass with the Delicate Air.

Letters to the Editor

TOO MANY DOCTORS?

SIR,—In your leading article of April 18, you raised the serious question of supply, demand, and placement of doctors in the future, and touched briefly on the matter of distribution. In this you stated: "The Medical Practices Committee emphasises the difficulties of attempting to predict future requirements of doctors in the present changing situation. Nevertheless the attempt should be made."

I would like to endorse your plea for such an attempt and stress the urgency of beginning at once in spite of the very obvious difficulties. In professional, and in lesser degree in economic, terms failure to make such calculations with reasonable accuracy is perhaps the greatest hazard facing the N.H.S. in the years ahead.

Too many doctors, or "bottlenecks" which slow down or prevent a steady professional advancement, thus artificially creating a state of over-supply at different levels in a planned medical service, are destructive not only to the morale of the doctors concerned but to the quality of the service as a whole.

An assessment of the supply of doctors needed should be attempted concurrently with the inquiry into the costs of the N.H.S. The two are intimately related (more so in the long run), and the one can lend force and direction to the other.

In approaching this problem of supply of doctors it would be desirable, in the first instance, to try to disregard the limitations and difficulties imposed by the existing administrative and legislative framework of the Act, and to concentrate on *real* needs. If these can be assessed with some accuracy—and I believe they can—it should be possible then to modify them in terms of the present Act, or better still to make intelligent modifications to the legislation and administrative machinery so that the *real* needs can be met. There is always a tendency to accept the existing terms of reference of a service like the N.H.S. as more or less immutable and to gear our thinking and predictions to these. If we concede to this tendency the terms soon do become unchangeable. One way to avoid this danger is to take stock about every five years, in absolute terms as suggested above, and then to review legislation and administration in this light. We have now reached this point and the need is apparent.

How difficult is the problem of predicting "future requirements of doctors in the present changing situation"? At the level of specialist services it should not be too difficult; certainly not so far as the hospital aspect is concerned. A great deal is now known about the incidence of illness requiring hospitalisation, the number of special and general hospital beds necessary per unit of population, and the specialists required to service a good modern hospital properly. This then becomes a big, but not too difficult, problem in statistics.

Predictions relating to general practice are much more difficult; and, before these can be made with any degree of accuracy at all, certain premises need to be established. How much and in what direction is general practice going to change? Are the present trends of more and more specialist services, and a lower and lower level of general-practitioner services, to continue? Will the general practitioner go on working alone or in a form of loose partnership agreement? Is properly planned and organised group practice to replace the inefficient and outmoded form of individual practice? Sound assessments of national requirements for general practitioners depend on answers to these questions. If they cannot be answered in absolute terms, it becomes necessary to establish certain theoretical assumptions and to make profession is not its skilled labour nor the citizen its raw material The medical profession is continuing within the service the work it was already doing before the service existed The citizen can use it or not as he sees fit A bad mistake was made at its christening—at once the consequence and the cause of much confused thinking "N M S," not "N H S," should have been its name, but at least we were spared "National Health Industry", and this is just as well, for if the "industry" conception prevails both doctor and citizen-patient must expect a curtailment of liberty in the interests of industrial efficiency far greater than that which occurs when a free, self-governing profession becomes a profession within a service

ALCOHOL PAIN IN HODGKIN'S DISEASE

Sir,—Not only Danish beer has the effect on Hodgkin's disease described by Professor Bichel and Dr Bastrup-Madsen (April 18)

In July, 1950, a man of 56 was referred to me because of severe hypogastric pain after drinking alcohol I could find no abnormality and advised him to stop drinking For five months he did so and had no pain, then he tried a glass of beer and was as bad as ever Because he had lost weight he came to see me again, and I found rubbery glands above both clavicles Biopsy, response to irradiation, and subsequent death were all typical of Hodgkin's disease

It seems odd that this striking symptom should not have attracted notice before this relatively abstemious age

London, W 1 **C P Petch**

Medicine and the Law

Alleged Negligence in Blood-transfusion

In Crawford *v* Board of Governors of Charing Cross Hospital [1] a practitioner was held to have been negligent in respect of the posture of the arm during a blood-transfusion The patient, a man aged 52, was undergoing a bladder operation, and for this purpose was placed in the Trendelenburg position with his head and shoulders lower than his pelvis His left arm was extended and secured at right angles to his body so that the transfusion could be given during the operation After the operation the extended arm was partially paralysed The right arm was already almost useless as a consequence of infantile paralysis in childhood

The patient sued the hospital governors, their servants or agents, for damages for the injury to his left arm Mr Justice Gerrard held that the operation itself had been completely successful and observed that allegations of negligence against the surgeon had been rightly withdrawn The only charge of negligence which had been proved, he said, was that the anæsthetist who administered the blood-transfusion had been at fault in the particular circumstances of the case in not avoiding the extension of the left arm "at any rate to the degree he permitted" for longer than was necessary The anæsthetist was in this respect negligent and his negligence had contributed to the very severe degree of brachial paralysis suffered by the plaintiff His Lordship assessed the damages at £4000, taking into account the evidence that the patient's state of health was very poor and that his expectation of life was no more than eight years Judgment, therefore, was given for the plaintiff, but a stay of execution was granted, pending appeal It would seem difficult, indeed, to establish the moment at which the extension of the patient's arm, if initially placed in a proper position, became negligent

Public Health

Smallpox

In the outbreak in Lancashire and the West Riding, the illness of a woman in Bury, mentioned in last week's report, has been confirmed as smallpox There have been no more cases and no more patients have died The total of confirmed cases is 26, including 6 deaths

First Quarter in England and Wales

The Registrar-General's provisional figures for England and Wales for the first quarter of 1953[1] show that the stillbirth-rate has fallen to a new low level and that the infant-mortality rate was the second lowest recorded for any March quarter There were 3597 stillbirths registered, giving a rate of 22 5 per 1000 total births, compared with 4146 and a rate of 23 3 per 1000 in the first quarter of 1952 (The figures for the first quarter of 1938 were 6185 and 38 3 per 1000) The infant mortality rate was 33 8 per 1000 live births, compared with 33 4 per 1000 in the corresponding quarter of 1952, which was the best March quarter on record The birth rate fell slightly to 15 8 per 1000 population, in the first quarters of 1951 and 1952 the rate was 16 3 and 15 7 per 1000 population respectively

Statistical Review of 1951

The medical tables included in the Registrar General's statistical review of England and Wales in 1951 were published this week [2] They contain detailed mortality statistics analysed by sex, age, and cause of death Many of the figures are also shown on a geographical basis The recent report of the chief medical officer of the Ministry of Health cited many of these statistics, some of which we mentioned in our summary of the report [3]

1952 in Eire

The birth-rate in Eire increased from 21 2 per 1000 population in 1951 to 21 8 per 1000 in 1952 [4] The infant mortality rate fell to 41 per 1000 registered births—the lowest figure yet recorded The death-rate of 11 9 per 1000 population was 2 4 less than in 1951 The decline in the number of deaths from tuberculosis continues, the death-rate in 1952 was 0 5 per 1000 population, and the figures for 1952 are less than half those for 1947

Pneumoconiosis in Boiler-scalers

Boiler-scaling is added to the occupations which are covered for pneumoconiosis under the National Insurance (Industrial Injuries) Act by regulations [5] made by the Minister of National Insurance Under these regulations, which came into operation on April 22, boiler-scalers who suspect that they have contracted pneumoconiosis may claim benefit under the Act

The Stratford Accident

At its meeting on April 23 the London County Council health committee expressed its appreciation of the work of the London Ambulance Service personnel who helped to deal with the accident on the London underground railway at Stratford on April 8 The mutual assistance arrangements between the L C C and the ambulance service authorities whose areas border on the County of London worked very effectively The committee was told that as a result of experience gained in the Harrow railway disaster in October, arrangements had been made to keep an ambulance, fully loaded with a comprehensive reserve supply of first-aid equipment, standing

logy (on duplicate smears); and (5) estimation of "radiation response."

Cytology certainly misses a small proportion of the cases of cancer of the uterus, but biopsies are not infallible. The methods are not rivals, and our gynæcologists have shown that they want the additional information and safeguard of the vaginal smear. I have been worried about the danger of occasional potentially misleading cytological reports. It was pleasing to learn that the three gynæcologists discount this entirely. We are agreed, however, that the cytologist must have proved his reliability in other fields of gynæcological pathology, and that the work cannot be left to beginners and technicians.

Vaginal cytology need not be confined to "larger teaching centres where adequate funds and skilled staff are available." The method is less expensive than bacteriology, and we have proved that hospitals can be served by the existing staff. The confusion again comes from cytology done for "cancer prevention clinics": the thought of checking every woman in the Kingdom once or twice a year certainly makes one shudder. That is very different from checking every woman who complains of some symptom that ought to be investigated.

We do not employ Papanicolaou's five classes because they give the impression that a woman may have "a touch of cancer," and that cytology can say how bad the disease is. Actually one of the greatest values of cytology is its inability to distinguish between carcinoma-in-situ and the most advanced invasive squamous-cell carcinoma.

You are also wrong in saying that "the diagnosis can only be provisional." In most, but not all, it is just as certainly a cancer cytologically as histologically. Cytology does not determine the extent of a tumour, its invasiveness, or its method of treatment.

I believe that you are also wrong in stating that there is continuous desquamation from the columnar epithelia of the cervix, endometrium, and fallopian tube; and in suggesting that cyclical changes in desquamated epithelial squames enable us to recognise the different phases of the menstrual cycle in humans.

Cytology comes into disrepute when it is practised by those who are inadequately trained, and when pretentious reports are made. I feel certain that in a few years from now no pathological laboratory will be considered good if it lacks a reliable cytology section.

Derbyshire Royal Infirmary, Derby.

G. R. OSBORN
Pathologist.

SIR,—In spite of the shortcomings of the vaginal smear technique, "its expense and the tremendous time it takes," a considerable literature in many languages has accumulated to testify to its value to the endocrinologist and the gynæcologist. The list of references and the summary account in your leading article might lead the reader to suppose that the method is designed for cancer detection alone.

Even if this one application be considered, the method deserves a wider trial than it has yet been given in this country. Five hundred hours spent "searching for an elusive cancer cell in vaginal smears" is well spent if that particular cancer could not have been detected clinically or by other means. What other diagnostic procedure can detect a cancer which is symptomless, which has not yet given a sign to indicate the site from which a biopsy may with advantage be taken, and which is, moreover, at a stage when it can almost certainly be eradicated? It is the question of alternatives that is of paramount importance when the value of a method is to be assessed, not its hypothetical cost in working hours. Who would care to put a price in working hours upon the life of his daughter or his wife?

London, W.C.1.

MARY E. EGERTON.

HAZARDS OF LUMBAR PUNCTURE

SIR,—In your leading article (April 11) you said that "the occurrence of headaches in 40% of ambulant patients in Sciarra's series confirms the idea that twenty-four hours' rest in bed is advisable after lumbar puncture."

Our experience is at variance with this statement and supports the findings of other authorities, especially those of Torbert,[1] who found the incidence of headaches after lumbar puncture to be 22% in inpatients, compared with 20% in outpatients, and Blau[2] who observed headaches in 22% of patients who rested at the clinic and at home, compared with 39% in those rested at home only and 13·6% in those who had no rest at all. Underwood[3] noted 25% headaches with eight to twenty-four hours' rest, 17% headaches with less than eight hours' rest, and 15% headaches with no rest at all; while Emory's statistics[4] showed that 39·5% had headaches with immediate bed rest, 38·8% had headaches with bed rest after four hours, and 35·5% had headaches with no rest at all.

In this department experience based upon control investigation over the past six years, has led us to believe that the majority of patients fare no worse if the twenty-four hours' rest is omitted. After allowing for the greater incidence of headaches in those with normal cerebrospinal fluids, we agree with Dattner,[5] who observed that absolute bed rest following lumbar puncture may result in more headaches than lively activity; and it is apparent that neither is effective in counteracting all the unpleasant sequelæ.

THE SENIOR REGISTRAR

SIR,—The letter from Dr. Forrester and Dr. Walton (April 18) draws attention to the senior registrar crisis, but seems to understate the magnitude of the problem. Their investigations have discovered 279 senior registrars in their fourth or subsequent years, with more returns still to come in. But what really matters is the number now in the market for consultant posts; and to estimate this, one must add to the 279 + the number now employed as research assistants or junior lecturers and the number of ex-senior-registrars who are not employed at all, or working from month to month as locums. It seems improbable that these luckless ones could figure in any regional board return; and, indeed, the only way of counting their heads would appear to be to ask them to write to the chairman of the Registrars' Group.

Young men are wise in their reluctance to embark on the long grind of specialist training, for there seems to be little comprehension among their seniors of the gross excess of men in training over prospective consultant vacancies. Consider a hospital where 15 consultants are employed. If appointed at the age of 35, a consultant's professional life is thirty years. The hospital will therefore have 15 consultant vacancies in thirty years, and should train 15 men to be consultants in that time. A senior registrar is appointed for four years; if the hospital employs only two senior registrars it will train 15 consultants in thirty years. Since a registrar is appointed for two years only, the number employed should be half the number of senior registrars if the appointment is to be regarded as the first step on the consultant ladder. No doubt there should be a slightly higher proportion of men in training to allow for early coronary thromboses among consultants and for consultant exports to a diminishing Empire. But

JOYCE WRIGHT.

CARDIAC ASTHMA

SIR,—Dr. Kynaston's comment (April 4) on his patient who had 67 attacks of cardiac asthma is surprising. That the condition should recur so frequently would appear to refute his conclusion that "morphine is the drug par excellence in cardiac asthma."

It is unusual for a hypertensive patient to survive the first attack of cardiac asthma for more than two years, but during this time attacks may not only be aborted but lessened in frequency by administering aminophylline, which has been shown to alleviate pulmonary congestion—perhaps most strikingly in hypertensive left ventricular failure, but no less effectively in aortic stenosis and mitral stenosis and also to a lesser extent in cor pulmonale.

Aminophylline (theophylline with ethylene diamine) is effective intravenously but of little use by any other route. My own practice in treating cardiac asthma is to combine injectio mersalyl *B.P.* 2 ml. with 18 ml. injectio aminophylline *B.P.* (containing 0·45 g. aminophylline), given during 10 minutes, provided that the patient has shown no intolerance of intramuscular mersalyl.

I should appreciate enlightenment as to whether my impression that slow intravenous injections of mersalyl are safer than quicker injections is well founded.

Guernsey. BRIAN WEBBER.

AN UNUSUAL TYPE OF HERNIA

SIR,—I have just read Mr. Howard's article (Feb. 21). This reminds me of a West African man of about 40 years of age on whom I operated two years ago in Nigeria.

> He had complained of pain in his left groin for 6 months and of swelling in each groin for many years. There were small, rounded lumps in each inguinal region over the site of the external ring; they were soft and partly reducible and had a cough impulse. At operation a mass of fat presented at the external ring. It was about 7 cm. in length and placed above the cord and separate from it. On dissection I found, to my surprise, that there was no hernial sac associated with the cord, but that there was a narrow sac inside the mass of fat; and this sac had its neck directed medially and its fundus laterally. It was in fact lying obliquely in the line of the inguinal canal, but with its neck at the external ring instead of the internal ring. Careful dissection of the neck showed that this passed through a small circular aperture in the conjoined tendon just deep to the place where the upper crus of the external ring meets the reflected inguinal ligament. Muscles and tendons were in good condition and the aperture had every appearance of being congenital in origin.
>
> The sac was too narrow to admit the little finger and was 6 cm. in length. A pair of artery forceps passing down the sac and through the neck entered the abdominal cavity in the direction of the fundus of the bladder, and the forceps could not be turned into any other direction while in this situation. The sac contained a little clear gelatinous fluid only and had evidently never been stretched by the entry of gut into it, at least in adult life. The cord and testis were of normal appearance and size. Operation on the other side revealed an identical type of hernia, and I could find no explanation why only one side had caused him pain. In each case, the sac was tied at the neck and removed, and the small aperture in the conjoined tendon closed by one stitch. This aperture was just medial to the pubic tubercle, and about 3 cm. above it.

This hernia had every appearance of being congenital, but I am quite unable to explain its site. After finding it I had plenty of opportunity to examine other cases of indirect inguinal hernia in Africans of the same tribe, but found nothing about their conjoined tendons to give a clue. It resembles in site a supravesical hernia, but I have so far found nothing in accounts of rare hernias that quite compares with it. The resemblance of this hernia with that described by Mr. Howard lies in the fact that both simulated indirect inguinal herniation and both came through minute openings in the transversalis and internal oblique muscle planes, although these openings were widely divergent.

TUBERCULOSIS IN GLASGOW

SIR,—There has been much speculation about the high incidence of tuberculosis in Glasgow, but a short visit by one not acquainted with local conditions will soon reveal some of the most important causes.

The housing conditions of many of the people are appalling by Southern standards. They have been described on many occasions. However, a visit with a general practitioner to an unselected patient in Anderson Ward revealed a little of this problem. The patient, a boy of six, the eldest surviving child in the family, was in bed in the "house."

> This was of the usual Glasgow type—one all-purpose room with the parents' bed in an alcove and another very small room just big enough to take the double bed in which all the children slept. The "house" was approached through a dark, damp corridor and then up three flights of the common stairway, ill lit, with a common lavatory on each floor. Off this floor five doors led to five "houses," each of which held a minimum of four people.

The patient, who had a temperature of 102°F, was ill with his sixth episode of bronchopneumonia. The mother was eight months pregnant and the father had just arrived home from Territorial Army training. He told us a little of their housing problem. They had been on the housing list for eight years. Twelve months previously, when the wife was in hospital having their fourth child, the rats were so troublesome that they took possession of the children's room and consequently the family slept in one large bed. Two days after the mother returned from hospital the newly born child was overlain and died. No open inquiry is held in Scotland in such circumstances. The parents assured me that their conditions were better than those of many others. Thousands of families live in such conditions, and it is to circumstances such as these that many patients return when hospital treatment for tuberculosis is finished.

I was amazed to learn that no consultant in tuberculosis had yet been appointed to the whole region of South-west Scotland, of which Glasgow is the centre. I met a doctor who as senior hospital medical officer is in charge of 350 beds and has many clinic responsibilities as well.

There has been little or no secondment of nurses from general hospitals to sanatoria or other hospitals where tuberculosis is treated. I was told that a doctor, prominent on administrative committees, had stated that if secondment from general hospitals was accepted he would withdraw his daughter from nursing. If this is the attitude which obtains in influential quarters there seems little hope of an intelligent approach to the nursing problem of tuberculosis.

Alleged Negligence in Blood-transfusion

IN Crawford *v* Board of Governors of Charing Cross Hospital[1] a practitioner was held to have been negligent in respect of the posture of the arm during a blood-transfusion The patient, a man aged 52, was undergoing a bladder operation, and for this purpose was placed in the Trendelenburg position with his head and shoulders lower than his pelvis His left arm was extended and secured at right angles to his body so that the transfusion could be given during the operation After the operation the extended arm was partially paralysed The right arm was already almost useless as a consequence of infantile paralysis in childhood

The patient sued the hospital governors, their servants or agents, for damages for the injury to his left arm Mr Justice Gerrard held that the operation itself had been completely successful and observed that allegations of negligence against the surgeon had been rightly withdrawn The only charge of negligence which had been proved, he said, was that the anæsthetist who administered the blood-transfusion had been at fault in the particular circumstances of the case in not avoiding the extension of the left arm "at any rate to the degree he permitted" for longer than was necessary The anæsthetist was in this respect negligent and his negligence had contributed to the very severe degree of brachial paralysis suffered by the plaintiff His Lordship assessed the damages at £4000, taking into account the evidence that the patient's state of health was very poor and that his expectation of life was no more than eight years Judgment, therefore, was given for the plaintiff, but a stay of execution was granted, pending appeal It would seem difficult, indeed, to establish the moment at which the extension of the patient's arm, if initially placed in a proper position, became negligent

Public Health

Smallpox

IN the outbreak in Lancashire and the West Riding, th illness of a woman in Bury, mentioned in last week' report, has been confirmed as smallpox There hav been no more cases and no more patients have died Th total of confirmed cases is 26, including 6 deaths

First Quarter in England and Wales

The Registrar-General's provisional figures for Englan and Wales for the first quarter of 1953[1] show that th stillbirth-rate has fallen to a new low level and that th infant-mortality rate was the second lowest recorde for any March quarter There were 3597 stillbirth registered, giving a rate of 22 5 per 1000 total birth compared with 4146 and a rate of 23 3 per 1000 in th first quarter of 1952 (The figures for the first quarter o 1938 were 6185 and 38 3 per 1000) The infant mortalit rate was 33 8 per 1000 live births, compared with 33 4 p 1000 in the corresponding quarter of 1952, which wa the best March quarter on record The birth rat fell slightly to 15 8 per 1000 population, in the firs quarters of 1951 and 1952 the rate was 16 3 and 15 per 1000 population respectively

Statistical Review of 1951

The medical tables included in the Registrar General's statistical review of England and Wales in 1951 wer published this week[2] They contain detailed mortality statistics analysed by sex, age, and cause of death Many of the figures are also shown on a geographical basis The recent report of the chief medical officer of the Ministry of Health cited many of these statistics, some of which we mentioned in our summary of the report[3]

1952 in Eire

The birth-rate in Eire increased from 21 2 per 1000 population in 1951 to 21 8 per 1000 in 1952[4] The infant mortality rate fell to 41 per 1000 registered births—the lowest figure yet recorded The death-rate of 11 per 1000 population was 2 4 less than in 1951 The decline in the number of deaths from tuberculosis continues, the death-rate in 1952 was 0 5 per 1000 population, and the figures for 1952 are less than half those for 1947

Pneumoconiosis in Boiler-scalers

Boiler-scaling is added to the occupations which are covered for pneumoconiosis under the National Insurance (Industrial Injuries) Act by regulations[5] made by the Minister of National Insurance Under these regulations which came into operation on April 22, boiler scalers who suspect that they have contracted pneumoconiosi may claim benefit under the Act

The Stratford Accident

At its meeting on April 23 the London County Council health committee expressed its appreciation of the work of the London Ambulance Service personnel who helped to deal with the accident on the London underground railway at Stratford on April 8 The mutual assistance arrangements between the L C C and the ambulance service authorities whose areas border on the County of London worked very effectively The committee was told that as a result of experience gained in the Harrow railway disaster in October, arrangements had been made to keep an ambulance, fully loaded with a comprehensive reserve supply of first-aid equipment, standing

23 chest clinics and survey units of the Bureau of Tuberculosis, these criteria were satisfied in 20 cases.

With 1 exception, the patients were between 19 and 31 years of age. 10 patients were negative to 1 mg. of Old Tuberculin, and 1 was negative to 0·01 mg., while 4 were positive to 0·01 mg. and 4 to 1 mg. (in 1 case no test was made). 18 patients had bilateral, and 2 unilateral, involvement. Paratracheal-gland enlargement was seen in 7 patients. In 11 patients who could be reviewed at sufficiently frequent intervals, complete disappearance of glandular enlargement was observed in from ten weeks to nine months. All of the patients studied for a mean period of five years have remained in good health, without evidence of recurrence or other visceral involvement.

During the last few years, only 3 cases of apparently asymptomatic hilar lymphadenopathy have been discovered in the Hull district by means of mass miniature radiography. These cases are being kept under observation, and if the numbers warrant it, they will be reported in more detail later.

Here, then, are some of the questions to be answered:

(1) How many of these cases are there in Great Britain? How many of these have (*a*) no symptoms; (*b*) erythema nodosum (excluding obvious cases of primary tuberculosis); and (*c*) clinical and histopathological evidence of sarcoidosis.?

(2) What is the age and sex incidence, and the reaction to tuberculin?

(3) Is there any seasonal incidence (as in erythema nodosum)?

(4) Why is the condition so much commoner in Scandinavia?

(5) Has this geographical difference any relation to the later age at which primary tuberculous infections tend to occur or to the more general use of B.C.G. in Scandinavia?

(6) Are some of these asymptomatic cases *formes frustes* sarcoidosis?

(7) What virus or bacterial infections can give rise to tuberculin-neutralising effects?

(8) What is the true value of the Kveim test?

Hull.

R. HERMON.

CIRCUMCISION OF THE NEWBORN

SIR,—Is there not a real danger of serious bleeding from hæmorrhagic disease of the newborn if circumcision is carried out at birth, as reported in your annotation last week? This danger may well have been the reason for ritual circumcision being delayed till the eighth day of life.

London, W.1. DAVID MORRIS.

ACRYLIC PROSTHESES

SIR,—In recent months a number of Judet acrylic prostheses have had to be removed from patients because of mechanical failure. These failures may be due to one or more of the following factors: (1) unsuitability of the materials employed; (2) design; (3) manufacturing methods; (4) sterilisation procedures; (5) position of insertion of the prosthesis and fit of the acrylic head in the acetabulum. In collaboration with Mr. J. M. Zarek, PH.D., of the faculty of engineering, King's College, University of London, experimental work is being carried out, the results of which it is hoped may shed some light on the cause of these failures.

The number of cases to which we have access is naturally limited. It would be of the greatest assistance if surgeons and pathologists who remove from a patient any prosthesis (which may or may not be broken) either at operation or post mortem, would be kind enough to send it to me at the Plastics Research Unit, Institute of Orthopædics (University of London), Royal National Orthopædic Hospital, Brockley Hill, Stanmore, Middlesex. The following information is required:

(*a*) A brief preoperative and postoperative case-history with the actual or estimated weight of the patient. Personal details which might identify the patients are not required.

(*b*) All radiographs in which the prosthesis can be seen. These will be returned.

(*c*) Details of method of sterilisation and, if possible, information on whether the prosthesis has been sterilised on a number of occasions.

(*d*) The prosthesis.

It is hoped that all those interested in this problem will coöperate, as an investigation of this kind can only be of value if as many as possible of the failures are investigated.

JOHN T. SCALES.

POLIOMYELITIS

SIR,—Your leading article of Jan. 10 has provoked several letters from orthopædic surgeons; and this is not surprising, as this leader exaggerated somewhat the recent views on treatment put forward by various people including myself.

I would, however, make a special plea to my orthopædic colleagues to widen their thoughts beyond muscle resting and the avoidance of deformity. The motor pathways in the spinal cord terminate in a pool of neurones, and each tract neurone communicates with many anterior horn cells. If, say, half of these cells are destroyed, the connections of this neuronal pool have to become extensively reorganised, and it is probable that the only effective method of getting the best out of this reorganisation is through the patient's determined and repeated attempts to move the muscle groups which appear to be paralysed. This provides a physiological explanation for the well-known fact that it is the patients who try hard who recover most. I would submit that the current orthopædic practice of discouraging activity in weak muscles for several months is likely to lose the opportunity to retrain the spinal connections in the optimum direction, and that under such methods the disconnected neurones of the spinal tracts are likely to be diverted more to muscles which are strong than weak, as the patient's spontaneous movements in bed are likely to be directed first to the movements he can make.

It is for such reasons that I and others advise early active movements to the weak and important muscle groups, which the patient practises himself after being shown how to do it. There is no substitute for the patient's will to move a muscle as far as the central nervous system is concerned. Fear of muscle fatigue after the acute stage has passed is quite unreasonable to the neurophysiologist, and simple muscle measurements easily confirm the harmlessness of deliberately induced fatigue in weak muscle groups at this stage.

Mr. Hyman (April 25) reports a remarkable case he saw in 1949, in which paralysis spread 5 weeks after the acute illness. However, his conclusion that this was due to the patient exercising too much is hardly justifiable. It is more probable that the patient had a second infection with another strain of the virus. Relapsing cases occasionally occur; but the second bout of paralysis very rarely, if ever, occurs at an interval of more than a week after the first has ceased to spread; it is for fear of this second spread that complete rest and heavy sedation seem to be so desirable for the first 2–3 weeks of the acute illness. It is conceivable that this period of 2–3 weeks should be prolonged a little if other cases like Mr. Hyman's are reported; but apart from his case, existing evidence suggests that complete rest for 2 weeks is long enough.

Department of Neurology,
Radcliffe Infirmary,
Oxford.

W. RITCHIE RUSSELL.

SIR,—I have been interested in the question of exercise in poliomyelitis since the 1947 outbreak, when I began tentatively to encourage active exercise during the third

Notes and News

EMPIRE RHEUMATISM COUNCIL

IN his report to the annual meeting of the Empire Rheumatism Council on April 29, Lord Horder, the chairman, remarked that in the past year the Council's research activities had been on a greater scale than ever before At the Hospital of St John and St Elizabeth, London, Mr A A Henly, PH D, assisted by Miss M I Potter, had continued research on steroid metabolism From this it seemed that there was no relation between urinary steroid excretion before treatment and the patient's requirements for A C T H or cortisone, but changes in the level of steroid excretion were fairly consistently related to the amount of hormone administered Experimental and clinical results had clearly shown the superior efficiency of A C T H given by continuous intravenous infusion instead of by intermittent injections Other investigators working under the ægis of the council included Dr J L Potter at the Northern General Hospital, Edinburgh, who had observed in cases of ankylosing spondylitis and rheumatoid arthritis that radiotherapy apparently caused improvement which could not be attributed to any direct effect of radiation on the diseased areas

The finance committee reported that in the year 1951–52 income amounted to *£16,965*, compared with *£20,332* in 1950–51 Expenditure totalled £14,553

COOPERATION IN THE HEALTH SERVICE

A YEAR ago the Ministry of Health proposed that a conference should be held to discuss measures for promoting coöperation between the administrative authorities of the National Health Service The London County Council and the regional hospital boards have since stated that they consider that liaison between the branches of the service is adequate, but they suggest that if any new consultative machinery is needed it should be based on hospital management committees The Metropolitan Boroughs' Standing Joint Committee also does not think it necessary to set up an independent consultative body, for it is satisfied with the present methods of cross representation, consultation between officers, and exchange of documents But it feels that there would be an advantage in councils having direct representation on H M C S At present, though councils are consulted about the membership of H M C s, there is no guarantee that their nominees will be elected At its meeting on April 23, the London Executive Council expressed its agreement with the views of the joint committee

AN UNNECESSARY VISIT

A PATIENT's offer to pay her National Health Service doctor a fee for a domiciliary visit made out of consideration for her convenience rather than her health was reported at a meeting of the London Executive Council on April 23 The patient stated frankly that she was well enough to go to her doctor's surgery, but preferred that he should visit her in her own home For this privilege she was willing to pay him a fee The Executive Council explained that the doctor by his terms of service was precluded from accepting such a fee, though he was free if he wished to visit a patient, even when it was not strictly necessary, he could make no charge for doing so The patient then referred the problem to the Ministry of Health on the grounds that, though the regulations forbade a doctor to accept payment for "medical treatment," travelling to a patient's home was not "treatment" The Minister, however, held that travelling was always involved when a doctor visited a patient and was part of the doctor's normal expenses on which his remuneration was based The Minister was unwilling to accept the responsibility for distinguishing between necessary and unnecessary visits and added that in his view to do so would "inevitably lead to misunderstandings, complaints and abuses, it would place a new and unwelcome burden of responsibility on doctors, and, at the same time, bring the Service into disrepute"

NEW PLANS AT OXFORD

BUILDING restrictions have hampered the growth of the clinical school established at Oxford in 1946, but there is now encouraging news The university and the board of governors of the United Oxford Hospitals have agreed in principle to a plan for building on the site of the Radcliffe Infirmary The plan awaits approval by the Ministry of Health It will strengthen the school in two ways Firstly, all the beds of the Nuffield professor of clinical medicine will be at the Radcliffe Infirmary, at present half of them are at the Churchill Hospital, where they are less useful for teaching The new department of clinical medicine will include improved laboratory accommodation Secondly, the board of the faculty of medicine has lately recommended that the next Nuffield professor of surgery, to be appointed in succession to the late Sir Hugh Cairns, should be a general surgeon, and the plan provides for a new department of surgery, also in the Radcliffe Infirmary, with about 50 beds, an operating theatre, and laboratories Both clinical research and teaching will benefit from the proposed changes The board of governors is making temporary arrangements, which will increase the number of beds at the Radcliffe Infirmary, until the new building is complete

OLD PEOPLE IN LIVERPOOL

ELDERLY Liverpudlians seem to be cautious of invoking statutory attentions, benevolent though these may be The Liverpool Personal Service Society, in conjunction with the department of social science of Liverpool University, during a survey [1] made between September, 1951, and January, 1952, found for instance that old people needing nursing care had not always applied for a nurse, though well aware they could have one if they liked They summed up their distrust in the remark "You never know what's for the best you might be worse off in the end" These independent tastes were probably responsible for the fact that the demand for social services among the elderly people was small Of the 500 interviewed—344 women over 60 and 155 men over 65 (in one case the sex was not recorded)—only 5 were found to be seriously short of friendly or neighbourly help

The old people visited were living in five areas in various parts of Liverpool The interviewers went from house to house in the areas chosen until they found they had visited 100 old people in each Only 47 of the 500 were living alone in houses or self contained flats, and only 42 alone in rooms, the rest were living with a spouse or with other relatives, or as members of families not their own Only 40 were out of touch with their relations, and 24 of these were living alone Most of them, however, had good friends or neighbours, or were visited by members of their church or club Indeed the interviewers record that they were not able to confirm the belief that services to elderly people are no longer rendered freely by good neighbours many of those visited had friends who called in at least once a day "to see that they were all right" Where there were family ties these were strong

Some old people, however, were lonely and unhappy at times, and the interviewers draw attention to the need for more friendly visiting of housebound old people, and because the recipients have no great enthusiasm for official visits, this visiting should as far as possible be arranged as a voluntary service, and done by people they know already Leaders of churches are urged to consider ways of increasing visiting of the old The old people's welfare committees, by encouraging the formation of clubs and community centres, can give more old people an interest in life for many of them are housebound merely because they feel there is nothing to go out for The visiting officers of the National Assistance Board, the surveyors suggest, might encourage those who appear lonely or isolated to join the appropriate church, club, or community centre of their region And these officers might also take the opportunity, it is thought, of tactfully reminding old people who are beginning to find their housework too much for them that an allowance is payable for domestic help and laundry where these are needed

Two unnecessary frustrations came to light which old people might well be spared Benches in the parks and pleasanter streets or open places give a target for a little walk and provide meeting places for cronies, but there are not nearly enough of them A modest outlay on benches by the local authority would bring many old people out in sunny weather, to the benefit of their health and spirits The other common frustration is over coal supplies one in seven of the old people had trouble, either because deliveries were irregular and the coal men pressed them to take several weeks' ration at a time, or because coal merchants refused to deliver coal upstairs or made an extra charge for doing so, or because the old people were not able to get or afford the full ration or the extra allocation for those over 75, or because they had nowhere to store coal These are points which the old people's welfare committees might well take up and set right

REMEDY FOR ANÆMIA

SIR,—Dr. Mennie (April 18) seems to think that most of the anæmic people in Britain today are getting too little food or the wrong sort of food. He also seems to believe that nutritional megaloblastic anæmias are common. Both these beliefs are erroneous.

In Britain today iron-deficiency anæmia is usually caused by pregnancy or by pathological bleeding, not by malnutrition. Most iron-deficient patients who fail to respond to iron salts by mouth respond quite well to saccharated iron hydroxide intravenously; they do not respond to liver or to folic acid. Slight differences in the speed of response to treatment are of little practical importance, because oral therapy with iron should be continued for some weeks even after apparent cure, and the dosage of intravenous iron is determined by the initial hæmoglobin level and the body-weight.

Nutritional megaloblastic anæmias are very rare. I have never seen that of pellagra nor that of infancy, and but 5 cases of megaloblastic anæmia of pregnancy among over 13,000 pregnant women. In Britain our common megaloblastic anæmia is pernicious anæmia, which is not a nutritional anæmia. Pernicious anæmia is better controlled by vitamin B_{12} than by liver.[1] It is well known that folic acid may precipitate subacute combined degeneration of the cord in a previously untreated patient suffering from pernicious anæmia. Suboptimal treatment of pernicious anæmia produces peculiar non-specific blood and bone-marrow changes which make diagnosis difficult or impossible.

Can Dr. Mennie wonder if I maintain that the remedy under discussion is unnecessary and probably dangerous, and that its introduction was against the best interests both of the patient and of the country?

Central Middlesex Hospital,
London, N.W.10.

GEORGE DISCOMBE.

CARCINOMA OF THE BLADDER

SIR,—The article by Mr. Winsbury-White (April 18) calls for some comment from radiotherapists.

I feel sure that nearly all radiotherapists have obtained good results from radon-seed implants, mostly, I admit, in non-infiltrating growths, but with a reasonable percentage of success in the infiltrating type confined to the bladder. Permanent disappearance of bladder cancer can be obtained also by well-planned X-ray therapy, including rotation methods. To attempt a bladder implantation without a good reserve supply of radon seeds is, of course, tragic; but this should never happen with adequate preliminary cystoscopy.

I would cite the five-year survival-rates in 95 patients published by the Holt Radium Institute, Manchester, in 1945:

Method	*Early*	*Late*
Cystotomy and intravesical radon..	59%	7%
X-ray therapy	60%	17%

London, W.1.

ANTHONY GREEN
Radiotherapist, Royal Northern Hospital.

SIR,—Mr. Winsbury-White's remarks about vesical papillomata interested and consoled me. I have been treating a woman, now aged 71, for this condition since 1931. Diathermy keeps her symptom-free. A short trial of podophyllin, applied locally, gave little relief to either party. An unusual complication afflicted another patient.

She first came under my care in 1933 when she was a patient in a mental hospital. Her age was 63 and she had undergone an open operation for vesical papilloma in 1928. Cystoscopy showed numerous papillomata covering the base of the bladder. These responded well to diathermy; her mental condition improved, and she was able to leave hospital.

She remained under regular observation and treatment until March, 1949. During this period she was known to have a lump, about the size of a walnut, in the suprapubic scar. She said there was occasional discharge from it but preferred not to have it examined. In January, 1944, she was admitted to a nursing-home bleeding freely from the tumour, which had increased in size. After a blood-transfusion had been given I excised the tumour, which was made up of two superimposed cysts with ossification in the walls. The pathologist's report was: "Implantation of papilloma into scar with calcification and ossification."

This patient made a good immediate recovery, but a few months later her mental disorder recurred, and she died with uræmic symptoms.

Northampton.

C. C. HOLMAN.

POLIOMYELITIS VACCINES

SIR,—Recent articles and reviews dealing with research on poliomyelitis virus and with poliomyelitis vaccines do not mention the work of G. Blanc and L. A. Martin at the Pasteur Institute of Morocco. These workers claim to have adapted the poliomyelitis virus (both the Brunhilde and the Lansing types) to the rabbit.[1] In this animal the virus causes a sharp febrile illness without paralysis, and the virus—recovered from the spleen—can be transmitted from rabbit to rabbit almost indefinitely.

The laboratory diagnosis of human non-paralytic poliomyelitis has been achieved by inoculation of the rabbit with specimens of fæces from the patients.[2]

These workers have also shown that this rabbit-fixed virus can be inoculated into hundreds of men, women, and children without any harm; and that when given in large quantities orally, it multiplies in the alimentary tract and behaves like an authentic poliomyelitis virus.[3] Admittedly their findings have not yet been confirmed, and they have yet to show that the rabbit-fixed virus can induce an active immunity against the human field-virus of poliomyelitis, but their work is full of so many far-reaching possibilities that it deserves at least a passing reference.

Park Hospital,
Hither Green,
London, S.E.13.

L. J. MAURICE LAURENT.

PROFESSIONALISM IN THE HEALTH SERVICE

SIR,—On Mr. Farrer-Brown's strictures (April 11) upon our professional standards and behaviour I would not dare to comment; but anyone, I think, is entitled to discuss whether the N.H.S. is an industry or not. Mr. Farrer-Brown says it is an industry "with the noblest of purposes." Wisely enough he leaves this purpose undefined; but, be it what it may, is not production, rather than purpose, the essential feature of an industry? Must it not have a product—coal, cocoa, or what you will?

What is the product of the N.H.S.? The only likely answer is "health" or "healthy citizens." But if this be so, why does it patch and keep alive so many cripples and "crocks," and why are not the homes, food, schools, occupations, and recreations of the citizens, on which their health chiefly depends, its foremost concern? I am sure the answer is that it is *not* an industry. Its supposed product, health, is only a by-product. If it is an industry, so are the educational services and the Royal Navy. It is a service, and not a health service but a medical service (or perhaps a medical and dental service).

It exists to give medical aid, comfort, and advice to those citizens who need or ask for it. The medical and fretful His skull circumference was $17\frac{1}{2}$ in and the fontanelle sunken There was no meningism Lumbar puncture produced purulent c s f, but organisms were not seen on direct smear and cultures were sterile

Intravenous fluids were started, and sulphadiazine 0 5 g six-hourly, penicillin 250,000 units six hourly, and streptomycin 100 mg b d were given The general condition improved a little, but the c s f remained abnormal, with increased cell and protein content A Mantoux test was negative in a dilution of 1 in 100

Towards the end of November it was noticed that the child's eyes had a fixed glazed appearance, the neck was slightly stiff, and there was a tendency to athetoid movements of the arms His head circumference was $17\frac{3}{4}$ in. Bilateral subdural taps were done, but no subdural fluid was obtained His general condition deteriorated, and on Dec 7 he had a generalised convulsion, which was controlled with chloral hydrate and phenobarbitone There were no further convulsions, but he lapsed into semicoma An air ventriculogram at this time showed severe symmetrical dilatation of both lateral ventricles and the third ventricle He was transferred to a neurosurgical unit for decompression, but died on Jan 2, 1952, before this could be done Necropsy was refused

Case 4 —A boy, aged 2 months, was admitted on Jan 1, 1952 He had been quite well up to the previous evening, when he developed a cough In the morning he refused his feeds and looked greyish A little later he had a generalised convulsion

On admission he was very ill and in respiratory distress His temperature was 98°F, his respirations were rapid and grunting, the alæ nasi were active, and there was slight cyanosis The eyes were rather staring, and there was an internal strabismus The anterior fontanelle was level and under normal tension, and there was no neck rigidity Kernig's sign was absent There was some diminished movement of the right lower chest, and crepitations were heard over the right lower lobe

TABLE II—SUMMARY OF CASES SHOWING NO "CLASSICAL" SIGNS OF MENINGITIS

Organism	No of cases	Symptoms					Recovered	Died
		Vomiting	Irritability	Anorexia	Drowsiness	Convulsions		
Meningococcus	3	0	1	2	0	1	2	1
Pneumococcus	2	2	0	0	1	0	1	1
Bact coli	4	2	1	0	0	0	0	4
H influenzæ	1	0	1	0	0	0	1	0
No organism isolated	3	1	2	2	0	0	2	1
Total	13	5	5	4	1	1	6	7

Treatment and Progress —Pneumonia was diagnosed, the child was put in an oxygen tent, and penicillin 50,000 units six hourly and sulphadiazine 0 25 g four hourly were given Next day the child was worse, and signs of bronchial spasm were noted in the right lower lobe, but otherwise the physical signs were unchanged and there was still no meningism. Streptomycin was substituted for sulphadiazine, and the dosage of penicillin was increased to 100,000 units six hourly, but his condition continued to deteriorate and he died on Jan 3

Necropsy —The meninges over the surface of the brain were covered with thick greenish pus The c s f was cloudy and contained numerous pus cells, with a few intracellular and extracellular gram-negative diplococci resembling

TABLE I—SUMMARY OF CASE-HISTORIES OF SEVEN INFANTS WITH NO "CLASSICAL" SIGNS OF MENINGITIS

Case no	Age	Symptoms before admission	Physical signs on admission	Treatment	Progress	Necropsy findings	Causal organism	Comments
7	$6\frac{1}{2}$ mos	Vomiting for 1 day	Acutely ill apathetic child in respiratory distress Signs of right upper lobe pneumonia Temp 102°F, fontanelle level, no meningism	Penicillin. Sulpha *dimidine*	Died 4 hr after admission	Purulent meningitis with flecks of pus in sulci and exudate over tip of temporal lobes and base of brain, lungs congested	*Bact coli*	Diagnosed post mortem
8	6 wk	Intermittent pyrexia for 5 weeks, failure to gain weight, relaxed stools	Wasting and dehydration No localising signs	—	Died 1 day after admission following a convulsion	Recent meningitis with opacity of basal meninges	*Bact coli*	In another hospital L P and subdural taps had been done with negative results, diagnosed post mortem
9	2 mos	Anorexia and irritability for 2 days	Irritability, facial pallor, mottling of body and limbs Temp 101°F, fontanelle level, no neck stiffness	Sulphadiazine. 'Eucortone'	Uneventful recovery	—	Meningococcus	L P done because baby looked more ill than could be explained by the physical signs
10	2 mos	Irritability, screaming attacks, and feverishness for 3 days	Fairly healthy looking baby Temp 99 6°F No localising signs Fontanelle level, no meningism	Sulphadiazine	Rapid recovery from meningitis, but convalescence prolonged by mild gastro-enteritis	—	Unknown	Sulphonamide given before admission, L P done because of history of irritability
11	6 wk	Irritability, vomiting relaxed stools and fever for 5 days	Ill child, slight dehydration, crepitations in chest, penile hypospadias Fontanelle level, no meningism	—	A few hours after admission had a left-sided convulsion and died about 10 hr later	Exudate over hemispheres, left kidney absent right kidney hypertrophied, containing abscesses, and ureter stenosed	*Bact coli*	Diagnosed post mortem
12	5 mos	Coryza and cough for 1 week, anorexia and pallor for 2 days	Pale fretful, drowsy, and wasted Temp 102°F, fontanelle level, no meningism	Sulphadiazine Penicillin	Vomiting caused dehydration Convalescence delayed by drip sepsis and anæmia Recovery complete	—	Meningococcus	—

Obituary

HERBERT STRINGFELLOW PENDLEBURY

M.A., M.B. Camb., F.R.C.S.

Mr. H. S. Pendlebury, consulting surgeon to St. George's Hospital, London, died on April 21, at the age of 82.

He was born at Wigan, the son of John Pendlebury, J.P. At Pembroke College, Cambridge, he was prizeman, exhibitioner, and scholar, and he took a double first in the natural sciences tripos in 1893. He entered St. George's Hospital with a university scholarship and he qualified in 1896, proceeding to the F.R.C.S. the following year.

After holding a demonstratorship in anatomy at St. George's, he was appointed to the staff in 1900. He also joined the staffs of the Royal Waterloo Hospital for Children and Women and the Kensington Dispensary and Children's Hospital. He held the lectureship on surgery at St. George's, and he was for some years a member of the court of examiners of the Royal College of Surgeons of England and an examiner for the University of Cambridge and the Society of Apothecaries.

Outside his surgical career Pendlebury was an administrator and organiser of considerable ability. With the late Dr. Arthur Latham he was largely responsible for the amalgamation of the London medical societies which led to the formation of the Royal Society of Medicine. He held the offices of honorary secretary and honorary treasurer in the early years of the society and in recognition of his services he was admitted to its exclusive honorary fellowship. Some twenty years later, as first honorary secretary of the Association of Surgeons of Great Britain and Ireland, he had the responsibility of the initial organisation of that body, whose progress from strength to strength he watched with interest all his life.

C. F., who was his first dresser at St. George's, writes: "Pendlebury retired from practice and from London about a quarter of a century ago, and there are not many left who knew him in his prime. To his generation he was a surgeon of great dexterity, quick and neat in his operating, and willing to take risks when needed. His punctuality was a byword among residents and students, who soon learned that it was wise to be ready at least five minutes before any appointed time. His teaching was clear and definite and left no doubt in the minds of the students as to the correct answer: in consequence his lectures and ward rounds were always fully attended or even overcrowded. To his friends and associates 'Pen' was a staunch colleague and he was always ready to help his juniors. On a holiday or at the dinner-table he made an ideal companion."

Mr. Pendlebury was twice married. His only child, the son of his first marriage, was killed in action in Crete during the late war.

JAMES THOMSON

C.B., C.M.G., M.A., M.B. Aberd.

Major-General Thomson, who held the appointment of deputy director-general of Army Medical Services in France at the end of the 1914–18 war, died in Aberdeen in April at the age of 90.

He was born at Udny, Aberdeenshire, and he graduated M.A. at the University of Aberdeen in 1883, and M.B. three years later. The following year he received a commission in the R.A.M.C., and in 1898 he took part in the Nile expedition. He received the British medal and the Egyptian medal with clasp for good service at the battle of Khartoum. During the 1914–18 war he was promoted colonel in 1915 and the following year he was posted to France. He served at first as D.D.M.S. to Hunter-Weston's VIII corps. In 1917 he was appointed C.B., and in 1918 when General Burtchaell became D.G. in succession to Sir Arthur Sloggett, Thomson, with the local rank of major-general, succeeded General "Tiger" Macpherson as D.D.G. At this stage of the war the Service hospitals were being bombed, and Burtchaell accordingly moved them further south. To Thomson at his headquarters at Hesdin was left the supervision of the casualty-clearing stations at the front and of the arrangements for the evacuation of the wounded. In 1919 he was appointed C.M.G. and a grand officer of the Crown of Rumania. He retired in 1920.

RICHARD MASSINGHAM

M.R.C.S.

Dr. Richard Massingham died at his home at Biddenden, Kent, on April 1, at the age of 55. He gave up medicine some years ago to give all his time to film production, but his old profession was the background and inspiration of much of his work in his new profession.

He was a son of the late H. W. Massingham, the well-known editor of the *Nation* and of the *Daily Chronicle*, and he was educated at University College and University College Hospital. After qualifying in 1924 he joined the staff of the old London Fever Hospital in Liverpool Road, Islington, where he became senior resident medical officer. He interested himself in the diagnosis and treatment of fevers and worked in collaboration with the late Dr. Charles Box, who was consultant to the hospital. In 1937 he published a paper on the Use and Abuse of Drugs in Acute Specific Fevers.

Following the artistic interests of his family, he started to make films as an amateur in 1932, and in 1934 he produced a full-length film entitled *Tell Me If It Hurts*, which showed the reaction of a patient to the dentist's drill. After he gave up his medical work in 1941 he made many films for the Ministry of Information and the General Post Office, and some of these were awarded international film distinctions.

"Both in his medical work and film production," writes G. A. H. B., "Massingham was a firm believer in the use of comedy and he always felt that no situation was too serious for laughter. In 1950, he produced a humorous film called *The Cure* which was based on his personal recollections of a visit by an eminent clinician and a pharmacologist. The clinician had recently visited Dr. Philip Hench at the Mayo Clinic, and while drinking the patient's sherry the visitors discussed cortisone and the pathology of rheumatoid diseases while the patient clutched his sides in pain. It was a charming and critical commentary on doctors and their patients, but unfortunately was shown only to a small audience. He was one of the most delightful and humorous men. Everyone who knew him must remember his roguish humour, coupled as it was with an acute and penetrating judgment."

Dr. Massingham is survived by his wife and an infant son.

Our obituary notice of Dr. Edridge-Green last week should have stated that he had two sons. One died in childhood and the other, a regular officer, in the 1914–18 war.

Appointments

Adam, John, M.B. Aberd., D.M.R.D.: registrar in radiology, Queen Mary's (Roehampton) Hospital, London.

Boothroyd, L. S. A., M.S. Lond., F.R.C.S.: senior surgical registrar, Exeter clinical area.

Harrison, G. J., L.R.C.P.I., D.P.M.: medical superintendent (consultant), Winwick Hospital.

Murray, David, M.B. St. And., D.P.H., D.I.H.: asst. M.O., Edinburgh school health service.

Newsam, P. N., M.B. Belf., D.P.H.: registrar in surgery, Mossley Hill Hospital, Liverpool.

Riley, Harold, M.B. Leeds, D.O.M.S.: part-time asst. (S.H.M.O.), eye department, The Children's Hospital, Birmingham.

Winter, John, M.B., M.RAD. Lpool, D.M.R.D.: consultant radiologist, Mill Road, Newsham General, and Bootle hospitals.

Newcastle Regional Hospital Board:

Caturani, Mario, M.D. Tufts, M.R.C.S., M.R.C.O.G.: consultant obstetrician and gynæcologist, N.W. Durham H.M.C. group.

King, J. M., M.B. Glasg., M.R.C.O.G.: consultant obstetrician and gynæcologist, Wansbeck H.M.C. group.

McClure, D. M., M.B. Glasg.: consultant pathologist, S. Shields H.M.C. group.

unwell, a blood-culture produced *Bact coli* The purulent meningitis found at necropsy was totally unsuspected

In cases 7 and 11 the infants were almost moribund on admission Their poor condition may have been responsible for absence of neck rigidity, but some increase in fontanelle tension might have been expected, especially in case 7, where there was no dehydration

In case 2 the child was dehydrated on admission, but after rehydration there were still no meningeal signs and the fontanelle was not under increased tension Lumbar puncture was performed because he seemed more ill than could be explained by the physical signs in the chest, and because of the disturbed level of consciousness and the convulsion

Although only 5 babies had convulsions at the onset of their illness, 9 others convulsed after admission to hospital Of the 14 who had fits, 8 died and 1 other later developed hydrocephalus and spasticity (mortality 57%), whereas of 36 babies who did not have fits only 3 died (mortality 8%) Prophylactic anticonvulsant drugs were not used as a routine The poor prognosis in infants with meningitis who develop convulsions has been emphasised by Ounsted (1951), and these figures strongly support his plea that all infants with meningitis should be given prophylactic anticonvulsant therapy

Of the 50 infants 11 died, and 7 of these, as already stated, were in the group showing no "classical" meningeal signs—which illustrates the serious prognosis among those that do not show the typical signs of meningitis All of the babies with *Bact coli* meningitis died, which agrees with the views of Randall (1948) and Ebsworth and Leys (1951) that the prognosis is poor in such infections

Descriptions of meningitis in most of the standard pædiatric textbooks do not emphasise the diagnostic difficulties For example, Wyllie and McKissock (1949) say "The onset is acute or subacute with fever 101–104°F, stiffness of the neck, muscular stiffness, Kernig's sign, twitchings, cutaneous hyperæsthesia, delirium and stupor", and Ellis (1951)

> "Stiffness of the neck is almost always present when there is meningeal involvement, but in young infants it is sometimes found that there is obvious bulging of the fontanelle with little neck stiffness Head retraction may be an early sign in infants Kernig's and Brudzinski's signs are positive
>
> Whilst the great majority of cases in early life are of abrupt onset, it is possible for the disease to appear more insidiously, with little pyrexia and few localising symptoms at the onset"

The series here reported shows that there may be no localising signs, even with an acute onset of the meningitis

"Meningism" may, of course, occur in cases without meningitis—e g, pneumonia (especially the apical type), urinary infection, and gastro enteritis

Absence of physical signs does not seem to be related to the site of the exudate In the 6 fatal cases with no meningeal signs in which necropsy was performed, the exudate was at the base of the brain in 4, around the spinal cord in 1, and mainly over the vertex in only 2 In 4 fatal cases with meningeal signs, the exudate was found around the base in all 4, over the vertex in 3, and around the cord in 1 Unfortunately the spinal cord was not examined in all the cases

In pneumococcal meningitis the lesions are mainly in the meninges of the brain, as a rule the spinal meninges are very little affected (Holt and Howland 1939, Nelson 1950) In pneumococcal meningitis, therefore, the distribution of the lesions might be the cause of absence of neck and spinal stiffness and Kernig's sign, which are presumably due to the irritation by inflammation of nerve-roots as they enter and leave the cord One case of pneumococcal meningitis in this series did, however, exhibit neck stiffness (table III) Increased tension or bulging of the fontanelle is a sign of increased intracranial pressure, but in the skulls of very young infants a moderate rise in pressure is compensated for by widening and separation of the sutures and fontanelles This compensation will be greatest in the very distensible skulls of newborn and very young babies, and will explain the absence of a bulging fontanelle in meningitis at this age In this series case 5 was the only baby under 1 month of age and she showed no such sign, and of 8 infants less than 2 months old, 3 had increased fontanelle tension and the other 5 did not, 4 of them forming part of the group of 13 without meningeal signs (table IV) A low-pressure state may occasionally develop in young infants in which the fontanelle becomes depressed and the bones of the skull may even overlap (Smith 1951)

Although the numbers of cases in each age group in table IV are too small for any definite conclusions to be drawn from them, the tendency for infants under 3 months of age to show "classical" signs less often than those in the older age-group is indicated

In conclusion, therefore, although increased tension of the fontanelle and neck stiffness may be found in infants with meningitis, they are often absent Kernig's sign is present in only about a quarter of cases and is of little value in diagnosis These cases show how varied the clinical picture may be, and "a high index of suspicion" is necessary if the mortality-rate is to be reduced Alexander (1947) goes so far as to say that stiffness of the neck and Kernig's sign are highly unreliable in the first few months of life and seldom appear before the advanced stage of meningitis She draws attention to the value of the signs of drowsiness alternating with irritability, a high-pitched cry, and a vacant look in the eyes in the diagnosis of meningitis in infants aged less than 7 months

Lumbar puncture should be done on any infant (1) who is unusually drowsy, or irritable, or has a "vacant look" in the eyes or a recent squint, (2) who is more ill than can be explained by the physical signs, or (3) who does not make the expected response to treatment for a disease such as pneumonia or gastro enteritis The "classical" signs of meningitis must not be waited for before this essential diagnostic step is taken

SUMMARY

In acute meningitis in infancy the "classical" signs of meningitis are often absent or appear late in the illness

Of a series of 50 cases of acute meningitis in infants under 1 year of age, 13 showed none of the "classical" meningeal signs 7 of these 13 cases were fatal

Review of the 50 cases supports the view that, in infants with meningitis, convulsions are of grave prognosis A plea is made for routine prophylactic anticonvulsant therapy in this disease

Delay in diagnosis is one of the main reasons why the fatality-rate of meningitis in infancy remains relatively high Diagnostic lumbar puncture should not await the development of typical meningeal signs

I wish to thank Prof N B Capon, Dr R W Brookfield, and Dr W E Crosbie for discussing this paper, and Dr S E Keidan for much help and advice

absent The blood pressure was normal Vaginal smears of a whole cycle showed a hyperœstrogenic curve Glucose tolerance was slightly reduced

The urinary output of 17 ketosteroids was 20 mg in twenty-four hours Chromatography showed a moderate excess of 11-hydroxy 17-ketosteroids (fractions VI and VII), with unbalanced excretion of gonadal katabolites excess of androsterone (fraction IV) and absence of its isomer (fraction V)

Case 5 —A girl, aged 18, complained in March, 1952, of recent abnormal growth of hair on the face The distribution of hair on face and pubis was typically masculine Her clitoris was moderately enlarged Other clinical findings were normal, including the general physique, which remained of a feminine type

The urinary output of 17 ketosteroids was 18–20 mg in twenty-four hours Chromatography showed an excess of etiocholanolone (fraction V) and a considerable quantity of 11 hydroxy 17 ketosteroids (fractions VI and VII) Glucose tolerance and insulin sensitivity were normal Vaginal smears gave a hyperœstrogenic curve

Case 6 —The twin sister of patient no 5 had the same trouble, the distribution of hair and the other clinical findings being exactly similar Sugar metabolism was normal

The urinary output of 17-ketosteroids was 22–25 mg in twenty-four hours Chromatography showed the same abnormal excess of fraction V, with large amounts of fractions VI and VII

TREATMENT

The treatment (fig 1) in cases 1–4 was with intramuscular cortisone 50 mg daily In case 3 it was continued in a dosage of 25 mg daily, followed by 12·5 mg daily In cases 5 and 6 cortisone was given by mouth, at first in a dosage of 50 mg daily, and later 25 mg daily

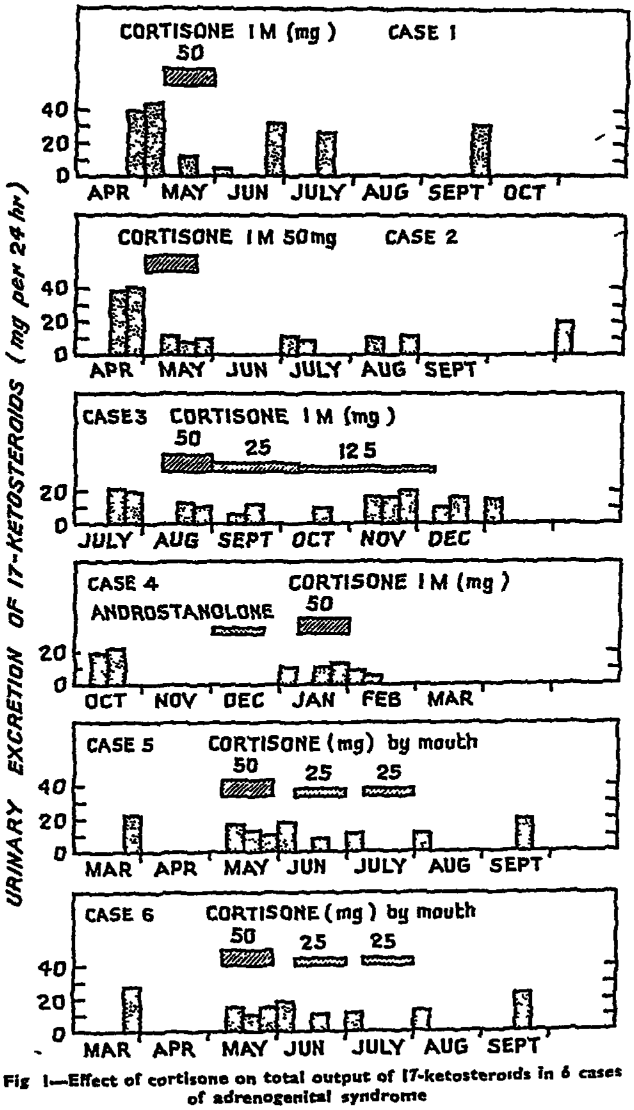

Fig 1—Effect of cortisone on total output of 17-ketosteroids in 6 cases of adrenogenital syndrome

TABLE II—INSULIN SENSITIVITY BEFORE AND AFTER CORTISONE THERAPY

Case no	Time	Blood glucose (mg per 100 ml) (% of fasting level)				
		Fasting	Time after insulin (min)			Greatest decrease (% of fasting level)
			20	30	60	
1	Before therapy	67	43 (64)	58 (87)	64 (96)	36
	" "	58	41 (71)	46 (79)	49 (84)	29
	4th day after end of therapy	47	14 (30)	5 (11)	14 (30)	89
5	Before therapy	70	37 (53)	50 (71)	70 (100)	47
	4th day after end of therapy	62	5 (8)	22 (35)	45 (73)	92
	9th day after end of therapy	75	35 (47)	32 (43)	51 (68)	57
6	Before therapy	74	62 (84)	74 (100)	80 (108)	16
	4th day after end of therapy	62	16 (26)	25 (40)	50 (81)	74
	9th day after end of therapy	47	16 (34)	12 (26)	47 (100)	74

RESULTS

Clinical

Wilkins et al (1950, 1951, 1952), Hubble (1952), and Jailer et al (1952) have shown that definite clinical improvement can be obtained only after protracted treatment Nevertheless even after short periods of cortisone therapy (the longest duration of treatment in our series was three months) some clinical results may be recorded development of breasts (cases 1 and 2), increased premenstrual tension in the breasts (case 5), and improved menstruation (cases 2 and 3) † In case 2 there was definite inhibition of hair growth, the patient having to shave only twice weekly instead of daily, and this clinical improvement lasted several months In cases 1 and 3 the patient had a dark complexion, in case 1 the quasi addisonian pigmentation was much reduced by cortisone therapy

Vaginal Smears

Before treatment the vaginal smears showed very few pyknotic and basophil cells in case 1, and an abnormally large number in case 4 In both cases the curves were without the usual inflections Under cortisone treatment a well marked cyclic inflection in the curves of both pyknotic and basophil cells appeared in cases 2, 3, and 4 In cases 5 and 6 cortisone restored the "hyperœstrogenic" curve to normal

Carbohydrate Metabolism

In cases 1, 5, and 6, after the end of treatment, the insulin sensitivity was considerably increased and a low fasting blood sugar level was observed (table II)

In case 4 cortisone had a definite diabetogenic effect the fasting blood sugar level rose from 64 to 83 mg per 100 ml and glucose tolerance was lessened

Urinary 17 Ketosteroids

The effect of cortisone on the urinary excretion of 17 ketosteroids is shown in fig 1 Daily doses of 50 mg and 25 mg given to these young adults had a definitely depressant action, whereas doses of 12 5 mg daily had no such effect The greatest effects were obtained in cases 1 and 2, where initial values were high

---

† Since this paper was submitted for publication, cortisone treatment has been resumed in case 1 25 mg was injected daily from September, 1952, till March, 1953, with the unexpected result that in this case of pseudo hermaphroditism, regular normal menses occurred on Dec 18, Jan 30, and March 3

THE DIAGNOSIS OF ACUTE MENINGITIS IN INFANCY

J. C. Haworth
M.B. Birm., M.R.C.P., D.C.H.

LATELY MEDICAL REGISTRAR, DEPARTMENT OF CHILD HEALTH OF THE UNIVERSITY OF LIVERPOOL AT ALDER HEY CHILDREN'S HOSPITAL

Although the prognosis in acute purulent meningitis in infancy has improved remarkably since the discovery and use of the sulphonamides and antibiotics, the fatality-rate is still alarmingly high. The report of the Department of Health for Scotland (1944) on "Sulphonamides in Meningococcal Meningitis" gave a fatality-rate of 28·3% in infants under the age of 1 year, compared with 2·6% in older children, aged 10–14. More recent statements indicate that the prognosis in meningococcal meningitis is little better now (Banks 1952), and it is noteworthy that, of 288 total deaths from meningococcal infection in England and Wales in 1949, 112 were of infants under 1 year of age and 202 were of children under 5 years (Registrar-General 1951).

One of the factors causing this high case-mortality is the delay in diagnosis of acute meningitis at this age. The classical clinical features, such as stiffness of neck and spine and Kernig's and Brudzinski's signs, are often absent in the early stages; or may appear at a time when treatment is no longer effective. Increased tension of the anterior fontanelle is a sign of the utmost importance; but this, too, may be absent, especially if the baby is at all dehydrated. This difficulty in diagnosis has been emphasised by Alexander (1947), Jackson (1950), and Smith (1951).

Present Investigation

Experience of several cases in which the diagnosis was made too late for effective treatment, or not until necropsy, prompted me to examine the case-sheets of the last 50 infants under the age of 12 months admitted to Alder Hey Children's Hospital with acute purulent meningitis. The admissions were between July, 1949, and April, 1952. The infection was meningococcal in 24 and pneumococcal in 5; in 4 it was caused by *Hæmophilus influenzæ*, and in 5 by *Bacterium coli;* and in 12 no organisms were isolated. Most of the unidentified infections were presumed to be meningococcal, many having been treated before admission.

The chief symptoms recorded in the routine admission history of the cases were:

Vomiting	31	Drowsiness	9
Irritability	28	Convulsions	5
Anorexia	16		

The physical signs were:

Neck rigidity	31
Tense or bulging fontanelle	22
Positive Kernig's sign	13
Squint or "vacant look" in the eyes	6

In 13 cases there were no signs of meningitis.

It must be stated that the observers were often junior house-officers, and perhaps more experienced pædiatricians might have noted evidence of meningitis in many more cases. Judgment of abnormal tension of the anterior fontanelle requires considerable experience of the normal.

Table II summarises the symptoms of the 13 cases showing no meningeal signs, and table III the signs and symptoms of the 37 cases showing obvious signs of meningitis in relation to the causal organism. Table IV summarises the signs and symptoms of the 50 cases in relation to age.

The case-histories of the 13 infants who showed no meningeal signs are reported, 7 in summary in table I, and the 6 others in more detail to illustrate the varied clinical picture of the disease at this age and the difficulties of diagnosis. Of this group 7 died, and in 5 the diagnosis was made post mortem.

Illustrative Cases

Case 1.—A girl, aged 3 months, was admitted on July 24, 1950. For five days she had been pale and listless and had been vomiting her feeds. She had had a cough for a few days.

On admission she was acutely ill, with a rectal temperature of 101°F. Respirations were rapid, the alæ nasi were active, there was slight intercostal indrawing, and occasional moist sounds were heard at both lung bases. The fontanelle was level and there was no neck rigidity. Kernig's sign was absent.

Treatment and Progress.—Pneumonia was diagnosed, and she was treated with sulphadimidine and penicillin. She remained very ill for a few days but then gradually improved; by July 29 her temperature was normal and her chest was clear both clinically and radiographically On July 30 fever returned, and twitchings of the face were observed. She became drowsy, and next day she had a generalised convulsion. There was still no neck stiffness or Kernig's sign. The cerebrospinal fluid (C.S.F.) was purulent, and pneumococci were grown on culture. Intrathecal penicillin 10,000 units was given on July 31, and again on Aug. 1. Neck rigidity was observed for the first time on Aug. 1 and even some head-retraction. Next day the C.S.F. was under very low pressure, which was not raised by jugular compression. Ventricular puncture was therefore done on Aug. 3, and penicillin 10,000 units was given into both ventricles. This was repeated on the next three days, but the child's condition deteriorated and she died on Aug. 6.

Necropsy.—Both frontal lobes were covered with a thick film of yellowish-green pus, and similar material was present in the basal cisterns and around the cord. There was a large hæmatoma in the left lateral ventricle, but no source of this hæmorrhage was found, and there was no evidence of excessive damage due to the ventricular puncture.

Case 2.—A boy, aged 3 months, was admitted on Oct. 18, 1951, with a day's history of irritability and refusal of feeds. There had been no previous illness.

On admission he looked very ill with a weak cry. His rectal temperature was 101°F. Severe dehydration and peripheral circulatory failure were evident. Scattered adventitia were heard in the chest. There was no neck rigidity, Kernig's sign was absent, and the fontanelle was level and not under increased tension.

Treatment and Progress.—Gastro-enteritis was diagnosed and intravenous fluid therapy started. Next day the temperature was still high. The baby was of good colour but drowsy, and became cyanotic when taken out of oxygen. Evidence of consolidation was present in the left lower lobe. He cried when disturbed but was not fully conscious. Later the same day he had a generalised convulsion, which was well controlled with chloral hydrate. Lumbar puncture produced opalescent C.S.F. under increased pressure and contained protein 80 mg. and sugar 89 mg. per 100 ml. Numerous pus cells and organisms resembling *H. influenzæ* were seen on direct film, but culture was sterile. Treatment with intrathecal and intramuscular streptomycin 100 mg. b.d. was started, and sulphadiazine 0·5 g. four-hourly was given by mouth. Intrathecal streptomycin 100 mg. was given daily for seven days, during which time the child's condition gradually improved, and the temperature fell to normal after five days. There were no further convulsions and eventually he made a full recovery.

Case 3.—A boy, aged 10 months, was admitted on Oct. 31, 1951. He was a twin and had been born three weeks prematurely after a normal pregnancy and delivery; his birth weight was 5 lb. 9 oz. For four weeks he had not been well with screaming attacks, diarrhœa, and vomiting. He improved for a time, but vomiting returned a few days before admission. His stools were then normal. He had been taking his feeds fairly well but refusing solids. His weight gain had been very unsatisfactory for several weeks.

On admission he was very fretful and weighed 16 lb. 12 oz. He was slightly dehydrated, but otherwise there were no abnormal physical signs. There was no neck rigidity or Kernig's sign.

Treatment and Progress.—He continued to vomit persistently and lost weight. On Nov. 16, he was dehydrated, irritable, with cortisone Some workers (Gardner and Migeon 1952, Bishop et al 1952) have measured the excretion of dehydro-iso androsterone in the adrenogenital syndrome treated with cortisone , but this single separation of one of the fractions of 17-ketosteroids may not have much significance Dehydro-iso androsterone (fraction III of the chromatogram) appears to be partly a result of hot acid hydrolysis of iso-androstenolone (Dingemanse's compound II), and an increased amount of it in the urine is no constant feature of the adrenogenital syndrome (Devis 1951b)

As shown by our chromatographic analysis in this disease, the output both of fractions II and III and of fractions V, VI, and VII may be increased Cortisone treatment definitely reduces the excretion of all these fractions, the effect being greatest on the fractions which are in greatest excess

SUMMARY

Six cases of adrenogenital syndrome treated with cortisone are reported

Clinical benefit was obtained decrease of hair growth in one case, regression of masculine physique in three cases, development of breasts in two cases, return to normal menses in two cases, and unexpected occurrence of normal menstruation in the case (no 1) of pseudo-hermaphroditism In one case skin pigmentation, resembling that of Addison's disease, regressed

The total amount of urinary 17-ketosteroids was much reduced in all six patients

Chromatography showed that this reduction affected all the adrenal fractions of the urinary 17-ketosteroids, especially those which were in great excess

The theoretical implications of these findings are discussed

" The life span being thus extended and healthiness being assured to the senescent, the relation between the chronological and the physiological age of the individual will need to be reviewed Manifestly the school-leaving age and the age on retiral in a population in which the life expectancy is 75 years might well be much higher than in one with a life expectancy of 45 years But there will be much need for knowledge on which the education of the middle aged in the art of growing old can be based, for senescents guidance clinics, for the development of a system whereby the process of withdrawal from society and from work as the power of adjustment and adaptation wanes is as gradual as the process of entrance into society by the infant "—Prof F A E CREW, F R S , in the Hastings lecture at the British Medical Association on May 6

ASSESSMENT OF PORTAL VENOUS HYPERTENSION BY CATHETERISATION OF HEPATIC VEIN

Myers and Taylor (1951) have described a method of estimating portal venous pressure by measuring the pressure in a catheter blocking a hepatic vein, and both they and Friedman and Weiner (1951) have shown that the technique is valid, at least in laboratory animals, by recording pressures from catheters placed simultaneously in the portal and hepatic veins The method is similar to that used by Dexter and his colleagues for measuring left auricular pressure with a catheter blocking a pulmonary arteriole (Hellems et al 1948) We have extended the technique of hepatic-vein catheterisation to study portal venous pressure in patients with liver disease

METHOD

Observations were made on fasting patients at rest ' Sodium amytal ' gr 3 (0 2 g) was given thirty minutes before the catheterisation Under fluoroscopic control a radio-opaque ' Nylon ' catheter was passed via an antecubital vein into a hepatic vein (Bearn et al 1951) The catheter was then advanced to the periphery of the liver until it met resistance about 10 cm beyond the mouth of the vein This was called the " occluded " position (fig 1) It was important at this stage to be certain that the catheter was passed to the periphery, since false records may be obtained if the catheter is obstructed at a venous junction

Pressures were then recorded by a strain gauge, the zero level being taken at a point 5 cm below the sternal angle with the patient supine Blood samples were taken from the occluded position for estimation of oxygen unsaturation, and the catheter was then withdrawn, under fluoroscopic control, about 5 cm to the "free" position (fig 2), where further pressure measurements and blood samples were taken If possible, the catheter was inserted into more than one hepatic vein radicle to obtain comparable pressure records Oxygen unsaturation was measured without delay on 5 ml samples by the Haldane blood gas apparatus

Catheterisation of a hepatic vein is not difficult and can be carried out in any centre equipped for cardiac catheterisation , it causes little discomfort to the patient, and the whole procedure rarely lasts longer than forty five minutes It is, moreover, as safe as right atrial catheterisation, and our experience totals 210 hepatic vein catheterisations without untoward incident

In some patients submitted to operation the opportunity was taken to measure the pressure in the portal vein more directly A ' Polythene ' tube, internal diameter 1 mm , was inserted at operation into a small tributary of the portal vein and tied in position , at the end of the operation it was brought out through a separate stab wound and stitched to the skin A drip containing physiological saline solution was used to keep the polythene tube patent , and, if necessary, other therapeutic fluids, including blood, could be given by this route In the first few days after operation pressures were measured with the strain gauge, and the polythene tube could then be removed without danger (Blakemore and Fitzpatrick 1951) meningococci. There was no bacterial growth on culture. The lungs showed patchy areas of collapse, especially in the left lower lobe, and an acute pyogenic bronchiolitis. Coliform bacilli were cultured from the bronchus of the left upper lobe. A left-sided hydronephrosis was present due to stenosis at the pelvi-ureteric junction.

Case 5.—A girl, aged 3 days, was admitted on Jan. 14, 1952. She was three weeks' premature and had been born after a normal pregnancy and delivery. Her birth weight was 5 lb. 11 oz. She was the first child of healthy parents, and there had been no stillbirths or miscarriages. She had appeared normal at birth, but jaundice developed a few hours later and deepened up to the time of admission. She had not taken her feeds well. Her stools had been normal in consistence and colour.

On admission she weighed only 5 lb. $3^1/_2$ oz. She was moderately jaundiced but not obviously anæmic, and she was quite vigorous. A few spasmodic contractions of the left orbicularis oculi were noted shortly after admission. The umbilicus was dry, the liver and spleen were not enlarged, and there were no signs of meningeal irritation. Bilateral cataracts were present.

TABLE III—SUMMARY OF CASES WITH "CLASSICAL" SIGNS OF MENINGITIS

Organism	No. of cases	Signs			Symptoms					Recovered	Died
		Increased fontanelle tension	Neck stiffness	Kernig's sign	Vomiting	Irritability	Anorexia	Drowsiness	Convulsions		
Meningococcus	21	13	20	8	16	16	5	2	1	19	2
Pneumococcus	3	2	1	0	1	2	2	2	1	3	0

H. influenzæ ..	3	2	3	1	3	1	2	1	1	3	0
No organism isolated ..	9	4	6	4	5	4	2	3	1	8	1
Total ..	37	22	31	13	26	23	12	8	4	33	4

Investigations.—Hæmoglobin 100% (14·8 g. per 100 ml.). A blood smear showed 104 nucleated red cells per 100 leucocytes. The blood-group was O, Rh positive. Reticulocytes 14%. The Coombs test was negative on two occasions. The serum-bilirubin level was 18·4 mg. per 100 ml. The Wassermann reaction was negative. Cold agglutinins were absent. The red-cell fragility was within normal limits. The urine was normal and contained no bile salts, bile pigments, or reducing substances. The mother's blood-group was O, Rh positive, and no antibodies were detected in the serum.

Course.—During the next few days the baby took her feeds well, but she vomited occasionally and her stools were rather loose. However, she gained weight slowly, and the jaundice was fading. On Jan. 26 there was only slight jaundice, but she looked pale. Her hæmoglobin was 73% (10·7 g. per 100 ml.), but it steadily decreased to 56% (8·2 g. per 100 ml.), and 150 ml. of blood was transfused intravenously on Jan. 30. Shortly after this she developed pyrexia and was obviously unwell. She began to lose weight and had more diarrhœa and vomiting. On Feb. 2 she suddenly had a generalised convulsion, which was controlled fairly well with chloral hydrate. Blood for culture was taken at this time and later yielded a growth of *Bact. coli*. Treatment with streptomycin 60 mg. b.d. was started, but she continued to have convulsions until she died on Feb. 5.

Necropsy.—A thick greenish exudate overlay the cerebellum and base of the brain. Culture grew *Bact. coli*. No abnormality or disease of the organs was found.

Case 6.—A girl, aged 4 weeks, was admitted on March 1, 1952. She was born at full term after a normal pregnancy and delivery and had weighed 6 lb. 7 oz. at birth. Shortly after birth she had a "cold," which rapidly cleared, and she was gaining weight steadily. On the night before admission she had vomited a feed, but otherwise seemed quite normal and went to sleep. In the morning she was heard to be making a "noise in her throat"; she looked pale and refused her morning feed.

On admission she looked rather ill and had a rectal temperature of 100°F. She weighed 8 lb. 2 oz. She seemed to be unaware of her surroundings, her respirations were grunting and distressed, and she had a high-pitched cry. There was a variable internal strabismus—sometimes with the right eye and sometimes with the left—and the eyes were making continuous roving movements. Both upper eyelids were a little retracted, showing a rim of sclera above the cornea. The left pupil was a little larger than the right, but both reacted well to light. There was no wasting or dehydration. The fontanelle was pulsating, flush with the scalp, and apparently not under increased tension. There was no neck rigidity, and Kernig's sign was absent. No other abnormalities were found.

TABLE IV—SIGNS AND SYMPTOMS IN RELATION TO AGE

Age on admission (mos.)	No. of cases	Signs			Symptoms					Recovered	Died
		Increased fontanelle tension	Neck stiffness	Kernig's sign	Vomiting	Irritability	Anorexia	Drowsiness	Convulsions		
0–1	1	—	—	—	—	—	—	—	—	—	1
1–2	7	3	1	1	4	4	2	—	—	5	2
2–3	5	2	2	1	1	3	3	1	1	4	1
3–6	16	10	11	7	8	8	7	2	1	15	1
6–9	12	6	9	2	10	6	3	3	2	8	4
9–12	9	1	8	2	8	7	1	3	1	7	2
Total ..	50	22	31	13	31	28	16	9	5	39	11

Treatment and Progress.—Lumbar puncture produced about 1 ml. of turbid C.S.F., which dripped out very slowly. Penicillin 10,000 units was injected intrathecally and 100,000 units intramuscularly, followed by 50,000 units six-hourly. The C.S.F. showed polymorphs and gram-positive diplococci on smear, and pneumococci grew on culture; pneumococci were also grown from a throat swab. Radiography of the chest showed consolidation at the right lung base.

Next day the child appeared a little brighter but was still taking feeds very reluctantly. There was no meningism. Lumbar puncture produced only a few drops of blood, but cisternal puncture produced turbid C.S.F. under normal pressure. Pencillin was again injected intrathecally. Only a very little xanthochromic C.S.F., with high protein content, was obtained by lumbar puncture in the next three days, but a free flow of C.S.F. was obtained on cisternal puncture, indicating a spinal block. Penicillin was given cisternally. On the seventh day a further lumbar puncture produced a free flow of almost clear C.S.F. under normal pressure.

The child remained febrile until the tenth day, but then made an uneventful recovery. Penicillin was given intramuscularly for fourteen days. The C.S.F. a week before discharge contained 35 leucocytes (mononuclears 60%) per c.mm. and protein 40 mg. per 100 ml. Radiography of the chest showed resolution of the pneumonia. When seen a month later in the outpatient department the child was very well and had progressed normally.

Discussion

Of the 50 cases studied, 13 (26%) showed none of the "classical" signs of meningitis, though both cases 4 and 6 had rather vacant and staring eyes and a squint. It was because of these signs in case 6 that meningitis was suspected and lumbar puncture performed. In 5 of the 13 cases (nos. 4, 5, 7, 8, and 11), meningitis was not diagnosed during life, and of the other 8 cases 1 and 3 were diagnosed too late for effective treatment.

Case 5 was especially interesting. The baby was admitted to hospital at the age of 3 days with moderately severe jaundice. No other signs were found apart from bilateral cataracts. The patient presented a difficult diagnostic problem because the usual causes of jaundice at this age were thought to have been excluded. Several blood examinations revealed no incompatibility between the baby's blood and that of the mother, the red-cell fragility was within normal limits, and the Wassermann reaction was negative. Although septicæmia was considered, it was thought improbable in view of the child's excellent general condition. However, when, after three weeks, the infant began to lose weight and was obviously

CORTISONE TREATMENT IN ADRENOGENITAL SYNDROME*

THE depressant action of cortisone on adrenal cortical secretion was first used by Wilkins et al. (1950) to correct the hypercorticism of pseudohermaphroditism in children; and the effects of this treatment in older patients with adrenogenital syndrome have been described by Wilkins et al. (1951, 1952), Bárrter et al. (1951), Thorn (1950), Bastenie et al. (1951), Laroche et al. (1952), Bishop et al. (1952), Simpson (1952), and Hubble (1952). The number of cases so far treated is small, and methods of therapy, dosage, and the mechanism of action of cortisone are still debatable.

We report here our observations in six cases of adrenogenital syndrome, including details of the different fractions of the urinary 17-ketosteroids, estimated by repeated chromatography before and after cortisone treatment.

MATERIAL, METHODS, AND TECHNIQUES

The patients, mostly ambulant, were studied partly during short stays at the clinic. The clinical examination included the anthropological measurements proposed by Decourt and Doumic (1950). The urinary output (total and fractionated) of 17-ketosteroids, the glucose tolerance (50 g. by mouth), the insulin sensitivity (intravenous insulin 0·1 unit per kg. body-weight), and vaginal smears were tested before, during, and three or four days after the end of cortisone therapy.

For the fractionation of 17-ketosteroids we used the chromatographic method of Dingemanse, as fully described by Dingemanse et al. (1952). The clinical interpretation of this fractionation has been discussed by Devis (1951a) and Albeaux-Fernet et al. (1951). Dingemanse's chromatographic analysis divides the urinary 17-ketosteroids into eight fractions, every one of which is composed of definite compounds most of whose chemical formulæ have been established (Dingemanse et al. 1952, Devis 1951a, Huis in't Veld 1948). Table I indicates their presumed relationship and origins.

The chromatogram of classical adrenogenital syndrome shows a heavy excess of fractions II and III (Devis 1951a, Dingemanse et al. 1946). When this syndrome is due to an adrenal tumour, fraction II nearly always accounts for at least half the total output of 17-ketosteroids. When it is caused by simple hyperfunction, typical adrenogenital syndrome may give a chromatographic pattern showing excess of fractions VI and VII (Devis 1951a).

The strict observance of Dingemanse's method as described by its authors allows us to apply the conclusions drawn from their chemical characterisations (Huis in't Veld 1948).

CASE-RECORDS

Case 1.—When first seen in 1947, at the age of 11 years, this girl had the typical features of android pseudohermaphroditism: accelerated body growth, muscular development, precocious epiphyseal ossification, early growth of sexual hair, progressive virilism leading to masculine aspect of the face and body, absence of breasts and vagina, and hypertrophy of the clitoris. Exploratory laparotomy revealed a small uterus and two large ovaries, a biopsy specimen of which showed a dense and strongly vascularised stroma, no germinative epithelium, but rare small primary follicles in the cortex.

In 1948 the left adrenal and two-thirds of the right adrenal, together with a small cortical adenoma, were removed. Microscopy showed enlargement of the reticular zone, which contained basophilic inclusions and brown pigment. After operation the clinical picture was not significantly changed, although the urinary output of 17-ketosteroids decreased, on an average, to 40 mg. in twenty-four hours.

Chromatography showed a heavy excess of fraction III, an insufficiency of fractions IV and V, and large, although still normal, amounts of fractions VI and VII. Insulin sensitivity was decreased (maximal decrease in glucose 30%).

Case 2.—A woman, aged 25, complained of scanty and irregular periods. At the age of 15 a masculine growth of hair had appeared on her face. In March, 1951, when she was admitted with acute appendicitis, definite virilism was detected: masculine gait and physique, male growth of hair on face and abdomen, undeveloped breasts, and a much enlarged clitoris.

The daily urinary output of 17-ketosteroids was 32·4–41·5 mg. Chromatography showed an excessive amount of 11-hydroxy compounds (fractions VI and VII) with androsterone and its isomer (fractions IV and V) at the lower normal limit.

Case 3.—This patient was first seen at the age of 18, when she complained of abnormal growth of hair on her face. She had begun to menstruate at 17, but her periods were irregular and scanty. She was of very dark complexion and moderately obese (weight 12 st. 4 lb., height 5 ft. $3^1/_2$ in.), with accumulation of fat greatest on trunk, shoulders, and thighs. Hirsutism was well marked on face and pubis. A few reddish striæ were seen on both flanks. The genitalia were normal, and the clitoris not enlarged, but the general physique was of masculine type. The blood-pressure (130/80 mm. Hg) and other clinical findings were normal. The fasting blood-sugar level and a glucose-tolerance curve were normal.

The total urinary output of 17-ketosteroids was slightly increased (19 mg. in twenty-four hours). Chromatography showed a great excess of fraction V (etiocholanolone) and a substantial output of 11-hydroxy compounds (fractions VI and VII), giving the curve the same shape as in Cushing's syndrome.

Case 4 was first seen in October, 1951, at the age of 25, complaining of abnormal growth of hair on the face, asthenia, and excessive menses. She was not obese (weight 9 st. 6 lb., height 5 ft. $4^3/_4$ in.). Her general physique was of masculine pattern, with large shoulders, slender pelvis, and long legs. There were moderate hirsutism on the face, a slight excess of body hair, and a typical masculine distribution of sexual hair. The clitoris was slightly enlarged. Striæ and osteoporosis were

---

* This work was supported by a grant from the Belgian "Fonds National de la Recherche Scientifique."

Fig. 2 shows how this action affected the different chromatographic fractions of the 17-ketosteroids. The excretion of the adrenal androgens (fractions II and III) was considerably inhibited in case 1, but in this case, as well as in cases 2 and 4, the effect was greatest on etiocholanolone and on 11-hydroxy 17-ketosteroids (fractions V, VI, and VII). In case 3 the action mainly affected fraction V, whereas it was masked for fractions VI and VII by the presence of cortisone katabolites, which are eluted in these fractions.

DISCUSSION

The results obtained by Wilkins et al. (1950, 1951, 1952) with several months' cortisone treatment have emphasised its practical value both in pseudohermaphroditism in children and in adrenogenital syndrome in young females. Our results obtained with a short treatment confirm those of Wilkins et al. and of Hubble (1952).

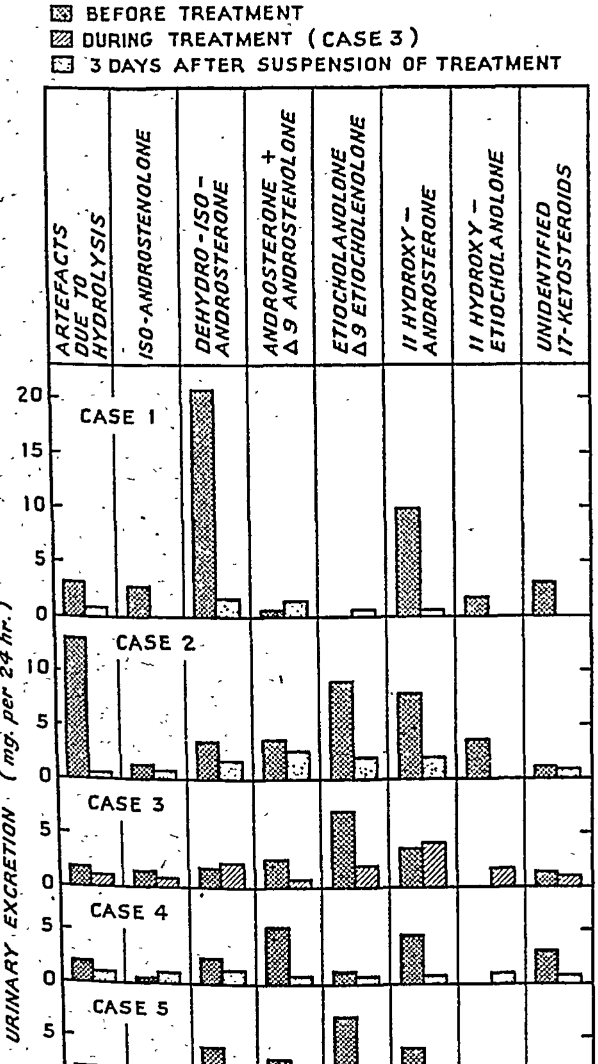

Fig. 2—Chromatographic analysis of urinary 17-ketosteroids in 6 cases of adrenogenital syndrome, with effect of cortisone shown in the first 4 cases. The absence of a histogram means none of the substance in question was found on analysis.

Wilkins et al. (1950, 1951, 1952) found that the smallest dose that would reduce the daily urinary output of 17-ketosteroids to 4–8 mg. a day was 25–50 mg. in infants and 50–100 mg. in older patients. The daily maintenance doses in patients aged more than 8 years were 25 mg. for intramuscular injection and 75 mg. for oral administration. In our cases 25–50 mg. by intramuscular injection sufficed to lower the output in adults to 10 mg. or less per twenty-four hours. This finding is in accordance with that of Hubble (1952).

Doses of 100 mg. or more, used by several workers (Bishop et al. 1952, Simpson 1952), may be unnecessary. Katabolites of the administered cortisone are partly excreted as 17-ketosteroids, which fact may account for an apparently insufficient decrease in urinary 17-ketosteroids when larger doses are used.

As shown in fig. 1, and as is evident from the observation of Bishop et al. (1952), adrenal cortical depression, judged by the urinary output of 17-ketosteroids, may last for several weeks. However, further experience will be necessary to ascertain whether oral administration of 25–50 mg. per day for twenty days each month is enough to depress cortical hyperactivity.

The suppression of adrenal cortical activity by cortisone treatment gives rise to interesting theoretical considerations. It is clear from anatomo-pathological findings, clinical investigations, and experimental studies that this effect is due to inhibition of the secretion of corticotropin (A.C.T.H.) by the pituitary gland. Barrter et al. (1951) suggest that two metabolic disturbances play a part in the pathogenesis of the adrenogenital syndrome:

1. A decreased ability of the adrenal cortex to respond to corticotropin, with an increased output of carbohydrate active steroids.
2. As a consequence of this abnormality, an increased production of corticotropin leading to abnormally high secretion of adrenal androgens.

According to Barrter et al. (1951) the biological and clinical features of adrenogenital syndrome are thus in sharp opposition to those of Cushing's syndrome.

Our observations do not seem to support this conception. Although some cases of adrenogenital syndrome and of Cushing's syndrome may give very different (nearly opposite) pictures, intermediate cases are common (see case 3).

In Hubble's (1952) case there was no evidence of deficiency of 11-oxysteroids "either under ordinary conditions or in response to A.C.T.H." Glucose-tolerance tests and insulin-sensitivity tests detected no such deficiency in the present cases. Further, in all our cases the urinary excretion of fractions V, VI, and VII was high, sometimes above the normal limit.

Fractions VI and VII are composed by 11-hydroxy-17-ketosteroids, especially 11-hydroxy-androsterone and its isomer 11-hydroxy-etiocholanolone. Fraction V contains a Δ^9 derivative of 11-hydroxy-etiocholanolone. These various compounds are believed to be metabolites of the glucocorticoids. They are absent in Addison's disease and are specifically increased both in Cushing's disease and in normal persons treated with corticotropin (Dingemanse and Huis in't Veld 1950).

Moreover, katabolites of cortisone administered to normal persons are eluted in these chromatographic fractions of 17-ketosteroids (Devis 1951b) (see fig. 2, case 3). Dobriner and Lieberman (1950) observed an increase of these substances during administration of "cortin." The occurrence, during steroid katabolism, of oxygenation in the C11 position of compounds which had no such oxygen is considered by these workers to be highly improbable.

Hitherto no attempt has been made to separate the various fractions of 17-ketosteroids in patients treated

Pressure tracings were measured by planimetry and represent the mean of the inspiratory and expiratory variations.

Readings were made in a group of patients without liver disease when catheterisation was otherwise indicated for a necessary assessment of cardiovascular, metabolic, or renal function.

RESULTS

Values for the occluded hepatic-vein pressure showed good agreement with those subsequently obtained from a portal-vein radicle (table I).

Pressure readings taken from different hepatic-vein radicles in the same liver also agreed well (table II).

The oxygen unsaturation of the hepatic-vein blood in 13 patients without liver disease was 59 ml. per litre, with a standard error of ±1·25, and in 9 patients with cirrhosis was 63·2 ml. per litre, with a standard error of ±8·2. There was therefore no significant difference between the oxygen unsaturation of the hepatic venous blood in patients without liver disease and in patients with cirrhosis.

Occluded Hepatic Venous Pressure in Portal Cirrhosis (Intrahepatic Portal Hypertension)

The occluded hepatic-vein pressure in this group was always greater than that in patients without hepatic disease (table III). The highest figure obtained in the latter group was 11·2 mm. Hg, and the lowest figure in a patient with portal cirrhosis was 15·4 mm. Hg; hence there was no overlap between the two groups. There was, moreover, a sharp gradient between the occluded and the free hepatic-vein pressures in patients with cirrhosis; and the sudden drop in pressure as the catheter is withdrawn can be well shown in a continuous tracing (fig. 3). Pressures in the free vein were usually slightly higher than similar pressures in patients without liver disease.

Case 1.—A housewife, aged 33, with post-hepatitis cirrhosis had ascites, spider nævi, and an enlarged spleen and liver two years after infective hepatitis. There was no radiological evidence of œsophageal varices. Liver-function tests showed positive flocculation tests and a reversal of the albumin/globulin ratio. Hepatic-vein catheterisation gave a high occluded pressure of 24 mm. Hg and a free pressure of 10 mm. Hg (fig. 3).

One patient with *hæmochromatosis* had an occluded hepatic-vein pressure of 15·6 mm. Hg, which suggests portal hypertension. Liver biopsy showed moderate fibrosis and distortion of lobules.

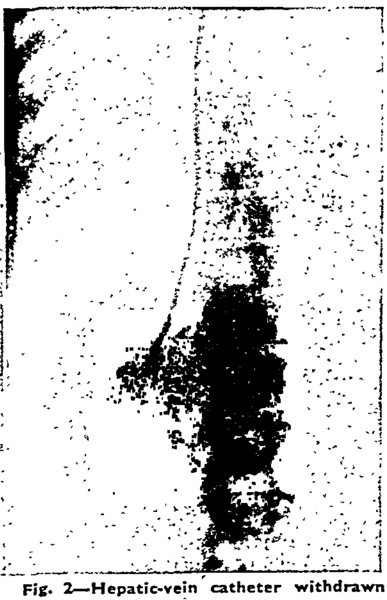

Fig. 2—Hepatic-vein catheter withdrawn to free position.

TABLE I—AGREEMENT BETWEEN PRESSURES OBTAINED FROM "OCCLUDED" HEPATIC VEIN AND FROM PORTAL-VEIN TRIBUTARY

Case no.	Pressures (mm. Hg)	
	Occluded hepatic vein	Portal-vein tributary
6	2·5	2·0
7	5·9	6·8
8	11·8	11·1
9	14·6	15·7

Extrahepatic Portal Hypertension

The occluded hepatic-vein pressure was normal in 3 patients with clinical evidence of portal hypertension. Extrahepatic portal obstruction was found at operation, and in each case the pressure measured in a portal-vein tributary was high. These patients are reported in more detail:

Case 2.—A girl, aged 16, with obliteration of the portal vein, had had recurrent hæmatemeses since the age of 13; gastroscopy revealed œsophageal and gastric varices. The spleen was enlarged. Liver-function tests and aspiration liver biopsy were normal. Hepatic-vein catheterisation showed a mean occluded pressure of 4·3 mm. Hg in three different hepatic-vein radicles (table II). At operation the portal vein was represented by a mass of tortuous dilated veins (fig. 4), and the mean pressure in a portal tributary measured postoperatively was 21·2 mm. Hg.

TABLE II—AGREEMENT BETWEEN OCCLUDED HEPATIC-VEIN PRESSURES MEASURED IN DIFFERENT RADICLES IN SAME PATIENT

Case no.	Occluded pressure (mm. Hg) in different radicles of hepatic vein		
	1	2	3
6	2·1	2·4	2·9
2	3·9	3·9	5·2
10	8·3	8·5	8·5
11	13·5	12·5	—
9	13·8	15·4	—
12	14·7	16·5	—
13	18·9	20·0	22·2
14	27·5	29·2	—

Case 3.—A lorry-driver, aged 43, with portal hypertension had had two severe hæmatemeses thought to be due to peptic ulcer, although radiography after a barium meal and gastroscopy were consistently normal. Liver-function tests and hepatic-vein pressures were also normal, the occluded pressure being 7·8 mm. Hg. Laparotomy revealed gastric and œsophageal varices, the cause of which was not found; the liver was normal. The pressure in a portal-vein radicle was 20·3 mm. Hg.

Case 4.—A man, aged 31, with hepatic cirrhosis, had undergone splenectomy six years previously for gastro-intestinal bleeding. Bleeding from œsophageal varices continued after operation. Hepatic-vein catheterisation showed a pressure of 11·7 mm. Hg in the occluded vein. At operation hepatic cirrhosis was seen and the portal vein was thrombosed. Direct measurement of the portal-vein pressure gave a very high reading of 39 mm. Hg. A portacaval anastomosis could not be undertaken.

This case demonstrates that, where portal thrombosis occurs in the presence of cirrhosis, normal pressures may be found in the occluded hepatic vein.

Obstructive Jaundice

In extrahepatic biliary obstruction both occluded and free hepatic-vein pressures were normal in 9 patients, none of whom showed evidence of biliary cirrhosis.

In intrahepatic biliary obstruction (primary biliary cirrhosis) in 3 patients the occluded hepatic-vein pressure was normal, and none showed clinical evidence of portal
